EDITOR-IN-CHIEF

Dr Roger A. Pielke is currently a senior research scientist in CIRES and a senior research associate at the University of Colorado-Boulder in the Department of Atmospheric and Oceanic Sciences (ATOC) at the University of Colorado in Boulder (November 2005—Present). He is also an emeritus professor of atmospheric science at Colorado State University and has a 5-year appointment (April 2007—March 2012) on the Graduate Faculty of Purdue University in West Lafayette, Indiana.

He has studied terrain-induced mesoscale systems, including the development of a three-dimensional mesoscale model of the sea breeze, for which he received the NOAA Distinguished Authorship Award for 1974. He has worked for NOAA's Experimental Meteorology Lab (1971—74), The University of Virginia (1974—81), and Colorado State University (1981—2006). He served as Colorado State Climatologist from 1999—2006. He was an adjunct faculty member in the Department of Civil and Environmental Engineering at Duke University in Durham, North Carolina (July 2003—06). He was a visiting professor in the Department of Atmospheric Sciences at the University of Arizona from October to December 2004.

He has served as chairman and member of the AMS Committee on Weather Forecasting and Analysis, and was the chief editor for the Monthly Weather Review for 5 years from 1981 to 1985. In 1977, he received the AMS Leroy Meisinger Award for 'fundamental contributions to mesoscale meteorology through numerical modeling of the sea breeze and interaction among the mountains, oceans, boundary layer, and the free atmosphere'. He received the 1984 Abell New Faculty Research and Graduate Program Award, and also received the 1987/1988 Abell Research Faculty Award. He was declared 'Researcher of the Year' by the Colorado State University Research Foundation in 1993. In 2000, he received the Engineering Dean's Council Award from Colorado State University.

He authored a book published by Academic Press entitled 'Mesoscale meteorological modeling' in 1984 with a 2nd edition in 2002, a book for Routledge Press entitled 'The Hurricane in 1990, a book (coauthored with W.R. Cotton) for Cambridge Press entitled 'Human impacts on weather and climate in 1995; 2nd ed., 2006, a book (coauthored with R.A. Pielke, Jr.) entitled 'Hurricanes: Their nature and impacts on society' published in 1997 by John Wiley and Sons, and was co-chief editor (with R.A. Pielke, Jr.) of a book entitled 'Storms' published by Routledge Press in 1999.

He was elected as a fellow of the AMS in 1982 and fellow of the American Geophysical Union in 2004. From 1993—96, he served as editor-in-chief of the US National Science Report to the IUGG (1991—94) for the American Geophysical Union. From January 1996 to December 2000, he served as co-chief editor of the *Journal of Atmospheric Science*. In 1998, he received NOAA's ERL Outstanding Scientific Paper (with Conrad Ziegler and Tsengdar Lee) for a modeling study of the convective dryline. He was designated a Pennsylvania State Centennial Fellow in 1996, and named the Pennsylvania State College of Earth and Mineral Sciences Alumni of the year for 1999 (with Bill Cotton). He is currently serving on the AGU Focus Group on Natural Hazards (August 2009—Present) and the AMS Committee on Planned and Inadvertent Weather Modification (October 2009—Present). He is among one of three faculties and one of four members listed by ISI Highly Cited in Geosciences at Colorado State University and the University of Colorado at Boulder, respectively.

He has published over 370 papers in peer-reviewed journals, 55 chapters in books, coedited 9 books, and made over 700 presentations during his career to date. The listing of papers can be viewed at the project website: http://cires.colorado.edu/science/groups/pielke/pubs/. He also launched a science weblog in 2005 to discuss weather and climate issues. This weblog was named one of the 50 most popular Scienceblogs by Nature Magazine on 5 July 2006 and is located at http://pielkeclimatesci.wordpress.com/.

VOLUME EDITORS

Dr Jimmy Adegoke is an award winning climate scientist whose research focuses on understanding the relationships between changing land surface processes and diverse indicators of environmental change. His recent work focuses on societal impacts of environmental change including air pollution studies in rapidly changing midlatitude urban areas and climate impacts on water resources in the Lake Chad Basin. He teaches at the University of Missouri-Kansas City (UMKC) where he served as chair of the Department of Geosciences from 2008–10. From August 2010 until very recently, he was Executive Director of the Council for Scientific and Industrial Research (CSIR) Natural Resources and Environment (NRE) Division, Pretoria, South Africa where he also served as the Director of the Applied Center for Climate and Earth Systems Science (ACCESS), a Center of Excellence (CoE) of the South Africa Department of Science and Technology (DST) Global Change Grand Challenge (GCGC) program. He is a member of several professional societies including the American Geophysical Union (AGU), Association of American Geographers (AAG), and American Meteorological Society (AMS). He is on the advisory council of the African Association for Remote Sensing of the Environment (AARSE) and also serves on the technical advisory committee of several United Nations applied science programs, including the United Nations Educational Scientific and Cultural Organization (UNESCO) crosscutting project on the application of remote sensing for water resources and ecosystem management in Africa. He lives in Kansas city where he served a 3-year team as an appointee of the Mayor of Kansas City Missouri (KCMO) on the city's Environmental Management Commission (EMC).

Dr Caradee Y. Wright is a senior researcher at the Council for Scientific and Industrial Research in the Climate Studies, Modelling and Environmental Health Research Group, leading the environmental health research team. She holds a PhD in public health from the University of Otago and an MSocSc in geography and environmental management from the University of Natal. Her research focuses on personal solar ultraviolet radiation exposure, personal dosimetry, health risk assessment, and skin cancer prevention. Recently, she has also worked in the field of air quality and finding ways to integrate public health into air quality management. She also works in the broader field of environmental health, leading large epidemiological, cross-sectional community surveys to consider the impacts of environmental pollution on community health and appropriate interventions. She is cochair of the South African Young Academy of Science, a member of the Global Young Academy, a council member of the National Association for Clean Air, and founder of the Environmental Health Research Network. In 2012, she was named one of 200 top young South Africans for her efforts to establish a SunSmart Research Programme and Lab in South Africa.

Dr Dev Niyogi is an associate professor with joint appointment in the Departments of Agronomy and Earth, Atmospheric, and Planetary Science at Perdue University.

He is also the State Climatologist for Indiana and Director of the Indiana State Climate Office. His research seeks to advance the understanding of vegetation and land surface processes in environmental, weather forecasting, and climate analyses, using a combination of dynamical models and surface, satellite remote sensing, and multiscale analysis products.

His research deals with the understanding and representation of the effects of vegetation – land surface processes in environmental processes at different scales. He is one of the three invited, nonfederal representatives to the community modeling effort of the Weather Research and Forecast (WRF) model working group on Land Surface Models, and to the Federal Geophysical Data Commission (FGDC) Spatial Climate Working Group.

He has authored or coauthored 25 successful proposals for external grants totaling over $3M. He vertically integrates undergraduate, graduate, and postdoctoral researchers in his research and is very interdisciplinary in developing collaborative projects.

Dr George Kallos is a professor at the University of Athens, School of Physics, Division of Environmental Physics and Meteorology. He leads the Atmospheric Modeling and Weather Forecasting Group (AM & WFG). He has a BSc from the University of Athens/School of Mathematics (1975). He obtained his MSc (1983) and PhD (1985) in Geophysical Sciences/ Atmospheric Sciences Division, Georgia Institute of Technology, School of Geophysical Sciences, USA. He has 110 publications in peer review scientific journals, more than 230 presentations and publications in conference proceedings publications, 10 contributions in books and more than 200 other publications in subjects related to atmospheric physics and chemistry, sea-state conditions, and renewable energy production. He has been invited 70 times to give talks in conferences, seminars, etc. His published work has received >2000 citations. He has participated in 80 projects. He has organized 12 conferences related to air pollution and dust transport in the Mediterranean. He has supervised 10 PhDs and over 100 MSc theses and participated in 20 PhD examinations in Greece and Europe. He is an associate editor for the journals: '*Environmental Fluid Mechanics*', '*Advances in Meteorology*', '*International Journal of Geosciences*', '*Atmospheric Pollution Research*', and '*Journal of Aerospace Operations*'. He was awarded the International Union of Air Pollution Prevention Association – IUAPPA award for his work on 'Long-range transport and air quality work in the Mediterranean region'. His current research activities are related to atmospheric, climatic, air pollution, and sea-state model development and forecasting. He focuses in fully coupled modeling systems. The latest model developments are related to nucleation processes in clouds, desert dust cycle and its direct and indirect effects. Research activities related to renewable energy resources (wind, ocean, solar) are focusing on high accuracy atmospheric model development, energy relationships and predictions, and protection from extremes.

Timothy Seastedt received his BA in biology from the University of Montana, an MS degree in biological sciences from the University of Alaska at Fairbanks, and a PhD degree from the University of Georgia. He was on the faculty at Kansas State University and is currently a professor of Ecology and Evolutionary Biology and fellow of INSTAAR at the University of Colorado, Boulder. Much of his research has been conducted as part of the Long-Term Ecological Research (LTER) programs at KSU and CU. His interests focus on terrestrial ecosystem ecology and the causes and consequences of biotic change. His recent activities have emphasized the ongoing changes found along the grassland to (melting) glacier gradient that exists in the Colorado Front Range.

Katharine Suding received her BA in biology from Williams College and a PhD degree from the University of Michigan. She was on the faculty at University of California Irvine and is currently a professor in Environmental Science, Policy and Management at the University of California Berkeley. Her background is in plant community and ecosystem ecology, with current interests in restoration, resilience, and environmental change.

Faisal Hossain received his PhD from the University of Connecticut in 2004. Prior to that, he had earned his MS and BS from the National University of Singapore and Indian Institute of Technology, Varanasi, respectively. He is currently an associate professor in the Department of Civil and Environmental Engineering where he received one of the highest awards of University – the Caplenor Research Award in 2012. His research interests comprise hydrologic remote sensing, uncertainty modeling of water cycle variables, human modification of extreme hydro-climatology, sustainable water resources engineering, space-borne transboundary water resources management, engineering education, and public outreach. He is also the recipient of awards such as NASA Earth System Science Fellowship (2002), Outstanding PhD Thesis Award (2005), NASA New Investigator Award (2008), American Society of Engineering Education (ASEE) Outstanding Research Award (2009), National Association of Environmental Professionals Education Excellence Award (2010), US Fulbright Faculty Award (2012), G.O.L.D. (Graduate Of the Last Decade) award from University of Connecticut (2012), and American Geophysical Union (AGU) Charles Falkenberg Award. He has published over 85 peer-reviewed journal articles, authored an undergraduate-level textbook, edited two book volumes, and contributed eight book chapters. His recent research on human modification of extreme events by artificial reservoirs has been featured by public media such as the BBC, National Geographic, New Scientist, Newsweek, Fox News, MSNBC, Wired.com, and German Public Radio. He served as an associate editor of *Journal of American Water Resources Association* from 2006–10. Currently, he serves as an associate editor for *Journal of Hydrometeorology* and a lead editor for the water volume of Elsevier Sciences five volume reference series on '*Climate Vulnerability: Understanding and Addressing Threats to Essential Resources*'.

PREFACE

We are pleased to introduce the five-volume set of books on bottom-up, resource-based vulnerability assessments of the societally and environmentally key resources of water, food, energy, human health and well-being, and ecosystem function. This inclusive bottom-up vulnerability concept requires the determination of the major threats to these resources from climate, but also from other social and environmental issues. After these threats are identified for each resource, the relative risk from natural- and human-caused climate change (estimated from global climate model (GCM) projections, as well as the historical, paleorecord, and worst case sequences of events) can be compared with other environmental and social risks in order to adopt the optimal mitigation and adaptation strategies.

The bottom-up, resource-based approach (referred to by O'Brien (2009) as ‘contextual vulnerability’) that is the focus of the volume is distinct from the Intergovernmental Panel on Climate Change (IPCC) top-down assessment of vulnerability based on the multidecadal GCM predictions (projections) which O'Brien defined as ‘outcome vulnerability’ (**Table 1** and **Figure 1**).

An excellent example of the contextual vulnerability is the paper by Romero-Lankao et al. (2012) who concluded in a study of the literature that urban vulnerability is dominated by epidemiological studies and top-down assessments, but that inherent urban vulnerability and urban resilience approaches (the contextual vulnerability) are what is required in order to illuminate a more complete set of drivers of urban vulnerability. They also showed that the large majority of papers on vulnerability use the outcome vulnerability approach. However, as discussed below, this top-down approach has major flaws.

First, there is the issue that the term ‘climate’ has two definitions. The broader view (and the one adopted by NRC (2005)) is that climate consists of the atmosphere, oceans, land, and cryosphere. This is the preferred usage. The second definition is that climate is the term used for the long-term (e.g., multidecadal) statistics of weather.

As reported in the NRC (2005) report and written in the Pielke et al. (2009) article with respect to human climate forcings.

> In addition to greenhouse gas emissions, other first-order human climate forcings are important to understanding the future behavior of Earth's climate. These forcings are spatially heterogeneous and include the effect of aerosols on clouds and associated precipitation [e.g., Rosenfeld et al. 2008], the influence of aerosol deposition (e.g., black carbon (soot) [Flanner et al. 2007] and reactive nitrogen [Galloway et al. 2004]), and the role of changes in land use/land cover [e.g., Takata et al. 2009]. Among their effects is their role in altering atmospheric and ocean circulation features away from what they would be in the natural climate system [NRC 2005]. As with CO_2, the lengths of time that they affect the climate are estimated to be on multidecadal timescales and longer.

and

> “…the natural causes of climate variations and changes are important, as are the human influences. The human climate forcings involve a diverse range of first-order climate forcings, including, but not limited to, the human input of carbon dioxide (CO2). Most, if not all, of these human influences on regional and global climate will continue to be of concern during the coming decades.”

Threats from climate involve any one or combination of climate variables as illustrated in **Figure 2**. There do not, of course, have to be changes in the statistics of these variables to constitute a risk. The term

Table 1 Contrast between a top-down versus bottom-up assessment of the vulnerability of resources to climate variability and change

Approach	*Comparative vulnerability*	*Contextual vulnerability*
Assumed dominant stress	Climate, recent greenhouse gas emissions to the atmosphere, ocean temperatures, aerosols, etc.	Multiple stresses: climate (historical climate variability, land use and water use, altered disturbance regimes, invasive species, contaminants/pollutants, habitat loss, etc.)
Usual timeframe of concern	Long-term, doubled CO_2 30—100 years in the future.	Short-term (0—30 years) and long-term research.
Usual scale of concern	Global, sometimes regional. Local scale needs downscaling techniques. However, there is little evidence to suggest that present models provide realistic, accurate, or precise climate scenarios at local or regional scales.	Local, regional, national, and global scales.
Major parameters of concern	Spatially averaged changes in mean temperatures and precipitation in fairly large grid cells with some regional scenarios for drought.	Potential extreme values in multiple parameters (temperature, precipitations, frost-free days) and additional focus on extreme events (floods, fires, droughts, etc.) measures of uncertainty.
Major limitations for developing coping strategies	Focus on single stress limits preparedness for other stresses. Results often show gradual ramping of climate change-limiting preparedness for extreme events. Results represent only a limited subset of all likely future outcomes — usually unidirectional trends. Results are accepted by many scientists, the media, and the public as actual 'predictions'. Lost in the translation of results is that all models of the distant future have unstated (presently unknowable) levels of certainty or probability.	Approach requires detailed data on multiple stresses and their interactions at local, regional, national, and global scales, and many areas lack adequate information. Emphasis on short-term issues may limit preparedness for abrupt "threshold" changes in climate sometime in the short or long term. Requires preparedness for a far greater variation of possible futures, including abrupt changes in any direction — this is probably more realistic, yet difficult.

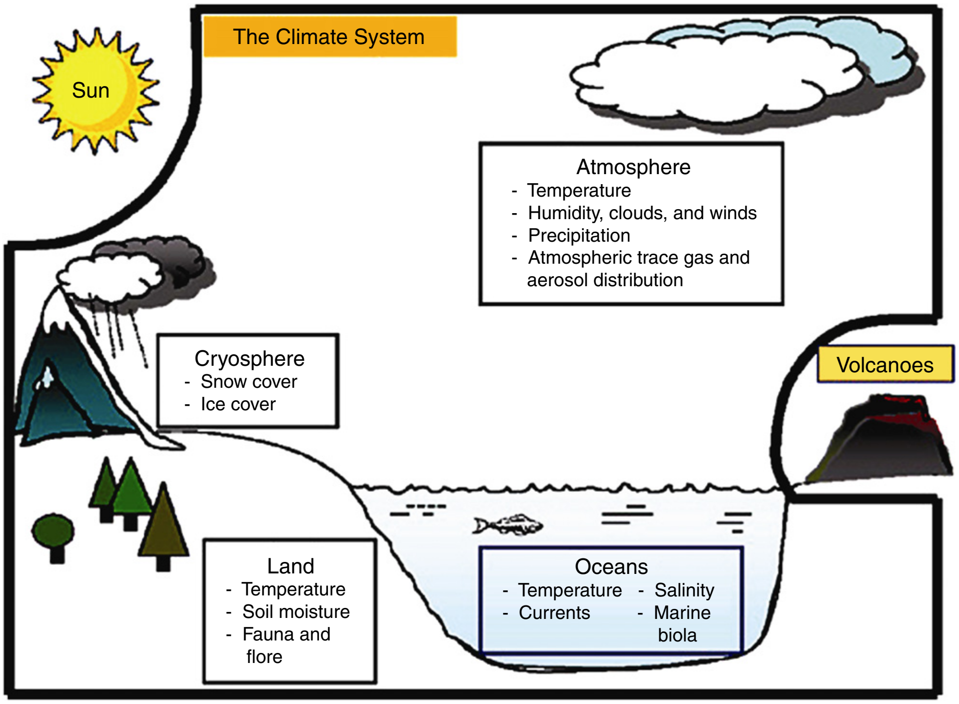
Figure 1 Framework depicting two interpretations of vulnerability to climate change: (a) outcome vulnerability and (b) contextual vulnerability. *From: Füssel (2009) and O'Brien et al. (2007).*

'climate change' should be used to describe any multidecadal or longer alteration in one or more physical, chemical, and/or biological components of the climate system, but as explained below, this terminology has morphed into multiple, diverse (and often mutually exclusive) definitions as used by the impacts communities.



The Climate System
Sun
Atmosphere
- Temperature
- Humidity, clouds, and winds
- Precipitation
- Atmospheric trace gas and aerosol distribution
Cryosphere
- Snow cover
- Ice cover
Volcanoes
Land
- Temperature
- Soil moisture
- Fauna and flore
Oceans
- Temperature
- Currents
- Salinity
- Marine biola

Figure 2 The climate system, consisting of the atmosphere, oceans, land, and cryosphere. Important state variables for each sphere of the climate system are listed in the boxes. For the purposes of this report, the Sun, volcanic emissions, and human-caused emissions of greenhouse gases and changes to the land surface are considered external to the climate system (NRC 2005).

First, climate is never static (Lovejoy and Schertzer 2012). As written in Rial et al. (2004)

> "The Earth's climate system is highly nonlinear: inputs and outputs are not proportional, change is often episodic and abrupt, rather than slow and gradual, and multiple equilibria are the norm."

The assumption of a stable climate system (e.g., the reason for the use of the terminology 'climate stabilization') in the absence of human intervention is a mischaracterization of the behavior of the real climate system. Humans are now adding to the complexity of forcings and feedbacks, but change has always been a part of the climate system. 'Climate change' is, and always has, been occurring. The added word 'change' is, therefore, redundant.

Moreover, there are additional misunderstandings. 'Global warming', which is an increase in the global annual average heat content measured in Joules, is often incorrectly equated to mean 'climate change'. Global warming, however, is just a subset of "climate change."

The term 'climate change', is also being erroneously used to mean only 'anthropogenic caused changes in climate' from nearly 'static' climatic conditions. Frequently, just the human input of greenhouse gases is assumed to be the reason for 'climate change'. For example, NRC (2010) (Climate Stabilization Targets: Emissions, Concentrations, and Impacts Over Decades to Millennia (2010)) states

> "This new report from the National Research Council concludes that emissions of carbon dioxide from the burning of fossil fuels have ushered in a new epoch where human activities will largely determine the evolution of Earth's climate."

Thus, the recommendations to the authors of the volume (not always accepted) were to replace terminology, such as climate change, climate stabilization, and climate disruption, with accurate terminology. When changes in climatic conditions are discussed, it was requested that the actual climate variables (such as temperature, precipitation, length of growing season) that are being altered, be specified. Phrases such as 'changes in regional and global climate statistics' could also be used.

There is a very fundamental reason to limit the use of 'climate change' by the impacts community. Key societal and environmental resources, such as water, food, energy, ecosystem function, and human health respond to climate, not just to an incremental change in the climatic conditions. As noted earlier, the assumption of a stable climate system, in the absence of human intervention, is a mischaracterization of the behavior of the real climate system.

However, some authors retained the use of the terminology 'climate change'. It was acquiesced as long as there was a significant contribution in their chapter to a broad-based assessment of risk to the key resource they were discussing.

Another misused term is 'global change', when really what is almost always meant is a local and/or regional change in the environmental conditions, including from climate. The accurate terminology should be 'environmental change'. The term 'environmental change' is, therefore, preferred rather than 'global change', as the latter terminology is very much a top-down viewpoint. Almost all impacts on key resources are on the local and regional scale.

We also requested the authors start with the risks and factor in the climate threats after thresholds, etc. were first obtained. This was not done in some chapters, but this information can still be extracted from the text. Obtaining the spectrum of risks first is the more inclusive way to assess threats to key resources, and thus, in the view, to prepare the optimal mitigation and adaptation strategies.

For the climate component of risk, the outcome vulnerability (the top-down) approach relies on skillful weather predictions and analyzes with a regional and a local focus. For weather prediction on time periods of days to a week or two, excellent skillful predictions are available for use in outcome vulnerability assessments. On seasonal timescales, there is also some limited predictive skill to apply to outcome vulnerability assessments, particularly for such well-defined weather events such as an El Niño or La Niña (Castro et al. 2007). However, for decadal and multidecadal predictions little, if any, predictive skill has been shown in hindcast climate model predictions of changes in regional weather statistics beyond what is available to the impacts community via the historical, recent paleorecord and a worst case sequence of weather events.

To illustrate the lack of skill, the conclusions from several papers have been summarized. Fyfe et al. (2011) concluded that

> "….for longer term decadal hindcasts a linear trend correction may be required if the model does not reproduce long-term trends. For this reason, we correct for systematic long-term trend biases."

Xu and Yang (2012) find that without tuning from real world observations, the model predictions are in significant error. For example, they found that

> …the traditional dynamic downscaling (TDD) [i.e. without tuning) overestimates precipitation by 0.5-1.5 mm d-1…..The 2-year return level of summer daily maximum temperature simulated by the TDD is underestimated by 2-6°C over the central United States-Canada region."

The paper van Oldenborgh et al. (2012) report just limited predictive skill in two regions of the oceans on the decadal time period, but no regional skill elsewhere, when they conclude that:

> "A 4-model 12-member ensemble of 10-yr hindcasts has been analysed for skill in SST, 2m temperature and precipitation. The main source of skill in temperature is the trend, which is primarily forced by greenhouse gases and aerosols. This trend contributes almost everywhere to the skill. Variation in the global mean temperature around the trend does not have any skill beyond the first year. However, regionally there appears to be skill beyond the trend in the two areas of well-known low-frequency variability: SST in parts of the North Atlantic and Pacific Oceans is predicted better than persistence. A comparison with the CMIP3 ensemble shows that the skill in the northern North Atlantic and eastern Pacific is most likely due to the initialisation, whereas the skill in the subtropical North Atlantic and western North Pacific are probably due to the forcing."

Anagnostopoulos et al. (2010) report that

> "…. local projections do not correlate well with observed measurements. Furthermore, we found that the correlation at a large spatial scale, i.e. the contiguous USA, is worse than [even] at the local scale."

Stephens et al. (2010) wrote

> "models produce precipitation approximately twice as often as that observed and make rainfall far too lightly…..The differences in the character of model precipitation are systemic and have a number of important implications for modeling the coupled Earth system …….little skill in precipitation [is] calculated at individual grid points, and thus applications involving downscaling of grid point precipitation to yet even finer-scale resolution has little foundation and relevance to the real Earth system."

van Haren et al. (2012) concluded from their study with respect to climate model predictions of precipitation that

> "An investigation of precipitation trends in two multi-model ensembles including both global and regional climate models shows that these models fail to reproduce the observed trends….. A quantitative understanding of the causes of these trends is needed so that climate model based projections of future climate can be corrected for these precipitation trend biases…. To conclude, modeled atmospheric circulation and SST trends over the past century are significantly different from the observed ones."

Sun et al. (2012) found that

> "…in global climate models, [t]he radiation sampling error due to infrequent radiation calculations is investigated …….. It is found that…. errors are very large, exceeding 800 W m^{-2} at many non-radiation time steps due to ignoring the effects of clouds…."

There is an important summary of the limitations in multidecadal regional climate predictions in Kundzewicz and Stakhiv (2010) who succinctly conclude that

> "Simply put, the current suite of climate models were not developed to provide the level of accuracy required for adaptation-type analysis."

Since the top-down outcome vulnerability approach depends on skillful decadal and longer regional and local climate predictions, yet they have shown little if any skill, another approach is needed.

For this reason, the volume set of five books presents an alternate approach – the bottom-up, resource-based outcome (contextual) vulnerability perspective. The goal of the set was to focus on the climate component of stress but also consider, in-depth, other environmental and social threats.

The text of the articles is written at a level that allows undergraduate students to understand the material, while providing active researchers with a ready reference resource for information in the respective field.

The questions requested to the authors address with respect to a specific resource were:

1. Why is this resource important? How is it used? To what stakeholders is it valuable?
2. What are the key environmental and social variables that influence this resource?
3. What is the sensitivity of this resource to changes in each of these key variables? This includes, but is not limited to, the sensitivity of the resource to climate variations and change on short (e.g., days), medium (e.g., seasons), and long (e.g., multidecadal) timescales.
4. What changes (thresholds) in these key variables would have to occur to result in a negative (or positive) response to this resource?
5. What are the best estimates of the probabilities for these changes to occur? What tools are available to quantify the effect of these changes? Can these estimates be skillfully predicted?
6. What actions (adaptation/mitigation) can be undertaken in order to minimize or eliminate the negative consequences of these changes (or to optimize a positive response)?
7. What are specific recommendations for policymakers and other stakeholders?

There are also overview chapters that discuss the science of the resource.

Several authors insisted on focusing on the use of the outcome vulnerability (top-down) approach based on the multidecadal GCM projections (statistically or dynamically downscaled) as the starting point of their chapters. The chapters were accepted, despite this shortcoming, because when they finally discussed adaptation in their text, they did present the broader-based bottom-up focus that is the centerpiece of the volume. Readers,

however, need to be aware that the top-down, GCM scenarios are only a subset, at best, of what is plausible in the coming decades. Multidecadal predictions of changes in regional and local climate statistics have not shown skill when run in a hindcast mode for the past several decades.

In summary, the goal of the five-volume set of books is to document the value of a bottom-up, resource-based assessment of risk to key resources, as illustrated schematically in Figure 3a–e. Most, but not all, authors accepted this framework. This can be assessed without having any predictability on

Preface - Vulnerability of Human Health to Climate

J Adegoke, University of Missouri – Kansas City, Kansas City, MO, USA
CY Wright, CSIR Natural Resources & Environment, Pretoria, South Africa

© 2013 Elsevier Inc. All rights reserved.

Human health, defined as the complete state of physical, social, and mental well-being and not merely the absence of illness, disease, or infirmity, is as vital a resource as water, food, or energy. Health underpins the economy of modern societies, providing employment for many in the health-care sector, and is an important driver of economic growth, accounting for a significant portion of the total expenditure as percentage of the gross domestic product in most countries. While a robust health-care system is needed to support a healthy society, broader actions to reduce social risk are vitally important, including efforts to reduce disparities in wealth, employment, equity, education, and housing.

Since the turn of the century, the public health landscape has become increasingly complex: old problems persist and new problems emerge – sometimes in unexpected places – and the importance of understanding economic, social, political, and environmental determinants of health has become more crucial. With health is now appreciated as a key driver of socioeconomic progress, commitment to the Millennium Development Goals (MDGs) will help to ensure that communities work their way out of poverty, contribute toward society, and enjoy improved quality of life while reducing their vulnerability and enhancing their coping mechanisms. Globally, progress toward the health-related MDGs and targets set for 2015 seem promising, but significant challenges remain because progress in addressing the needs of the most vulnerable has been slow. The MDGs, adopted as part of the UN Millennium Declaration by 189 heads of state in 2000, articulate targets for countries to reduce poverty and hunger; tackle ill-health, gender inequality, lack of education, and environmental degradation; and improve access to clean water. In 2011, reports of indicators measured suggested that, globally, fewer children were dying, fewer children were underweight, fewer people were contracting HIV, tuberculosis treatment was more successful, and more people had safe drinking water but not adequate sanitation. This progress was not evenly spread across all countries, with some making excellent progress and others falling behind, especially those countries affected by the HIV epidemic, conflict, and poverty.

Within countries, the capacity of communities to cope with health-related risks differs significantly; thus, communities have different susceptibilities to illness, disease, and infirmity. Their vulnerability may be further complicated by social, economic, and environmental issues. Poverty and inequity are major challenges to public health; environmental stresses such as droughts, excessive heat, and floods are a compounding challenge. Climate-induced vulnerability is one of several threats to public health with several direct and indirect impacts. These range from the direct physiological effects of heat and cold on the human body to adverse effects on livelihoods resulting in poor health outcomes. Some of the direct

climate-related health effects, risks, and impacts include water- and food-borne diseases and heat-related morbidity and mortality. Although the editors of the Health Volume of the Climate Encyclopaedia attempted to achieve comprehensive coverage of climate-related health impacts, the contributions included in the volume, of course, reflect the expertise and interests of the team of health and environmental experts that authored the chapters.

The Health Volume of the Climate Encyclopaedia was compiled in three parts. Part one considers cross-cutting environmental threats to human health. These threats include extreme weather events, stratospheric ozone depletion, sea level rise, ecosystem change, floods, droughts, and biodiversity loss. Part two focuses on the relevant health effects, impacts, and risks posed by these threats. Health impacts explored in this section include food-borne disease and malnutrition, heat- and cold-related morbidity and mortality, urban air pollution, and respiratory allergy, HIV, TB, and occupational health. Part three uses the case study approach to examine theme- or place-specific topics that offer unique insights, which also have broader relevance. The section includes three case studies. The first is a bibliometric analysis of keywords 'human health in a changing climate' in academic literature over the past three decades, showing that this topic has become an attractive research and media topic. The second case study explores the food insecurities experienced by Pacific Island countries to highlight the complexity of vulnerabilities over and above those related to climate vulnerability. The third case study focuses on Africa and shows how health outcomes are a key determinant of social or contextual vulnerability using a South African community-scale example.

Given the complexity of factors that influence human health, assessing health impacts related to climate clearly poses a difficult challenge. Nevertheless, we sought in this volume to present a well-rounded picture of both the threats and risks to human health posed by climate, in the widest possible context and applying a contextual vulnerability approach, thereby providing material to aid in public education, planning, and decision making at all levels. A great effort, for which the editors are deeply grateful, was made by all of the Health Volume authors to apply a contextual vulnerability and a bottom-up approach in the presentation of their subject material. Our hope is that this will give readers a holistic understanding of each issue and also make it easier for decision makers in the health sector to incorporate ideas and concepts presented in this volume in their community risk assessment and adaptation planning efforts. The editors also wish to acknowledge and thank all the anonymous chapter reviewers for their time and effort to meticulously review the content for technical and scientific accuracy.

1.01.1 Introduction

The term ‘global warming’ is largely recognized by the general public as an increasing annual average global surface temperature. This is often perceived to be the only result of the increased emissions of greenhouse gases from human activities. ‘Climate change’ is now the term often used to describe the effects of these emissions on our environment. Global warming is a part of climate change, along with changes in weather patterns, sea level, and so on. However, regional temperature extremes (cold surges and heat waves), in association with increased variability in severe weather events such as hurricanes, are the more important aspects of climate change. These affect societies and ecosystems more directly than does the global climate average.

As with all weather phenomena, the impacts of climate will depend on the systems in which it occurs. Weather-related events and climatic extremes can have disastrous effects on the environment, human society, and infrastructure. For human systems, much will depend on our ability to adapt to these events and extremes. Changes in crops, infrastructure designs, and many other aspects of society can greatly increase resilience to adverse weather as well as reduce the risk to climate variability and long-term change. Yet the capacity to adapt to climate is much greater in particular groups, for example, developed countries as opposed to underdeveloped countries, and so the effects of climate and extreme weather events vary regionally and even between groups within a particular society. This chapter examines the effects of extreme weather events on human health and health systems, people’s vulnerabilities to extreme weather, and their coping capacities.

1.01.1.1 Climate and Extreme Weather Events

Climate change includes a change in the state of the climate that can be identified (e.g., using statistical tests) by changes in the mean and/or the variability of its properties and that persists for an extended period, typically decades or longer. It refers to any change in climate over time, whether due to natural variability or as a result of human activity (IPCC 2007). Extreme weather is weather that is outside of what is normally expected for a particular location and thus is rare for that area. Therefore, these areas are often not prepared for these events, and extreme weather events can cause severe damage to the environment, infrastructure, and human society. This can be costly both in a monetary sense and to life. A significant effect of humans on the climate has been accepted by most of the scientific community. Such a human effect could increase the frequency, severity, duration, or aerial extent of extreme weather events. However, actual trends in extreme weather events are difficult to determine, given the complications such as lack of long-term climate data, spatial variation in data available, and changes or differences in public perception (e.g., there is an increase in media access, thus the public is more aware of extreme weather event occurrences).

Determining trends in extreme weather events is also difficult because extreme events by definition are rare. However, there is empirical evidence that extreme weather damage has become more frequent and/or more severe (Figure 1) and it is now concluded that the reason for most of the increased damage is socioeconomic, not climate, at least up to the present. There has been a dramatic increase in the number of disaster events over the past decade and a geometric increase in the number of people affected since the beginning of reliable recording in the 1960s

http://dx.doi.org/10.1016/B978-0-12-384703-4.00103-9

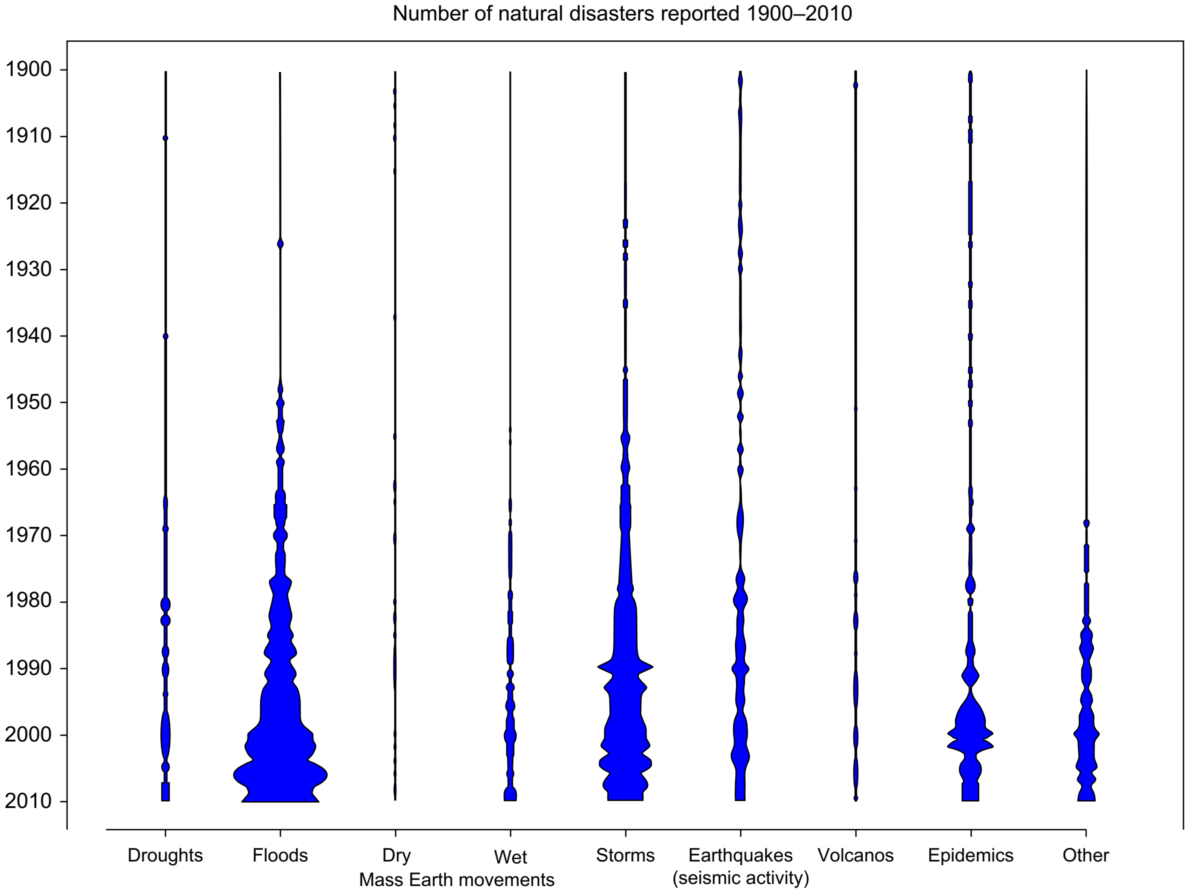

Figure 1 Number of natural disasters reported 1900–2010. Source: EM-DAT: The OFDA/CRED international disaster Database – www.emdat.be, Université Catholique de Louvain, Brussels (Belgium).

(IFRC 2003). There have been claims of increasing frequency of heavy precipitation events in the midlatitude regions that has been linked to global warming (Groisman et al. 2005).

Extreme precipitation events may lead to more intense and frequent river flooding. In other areas, for example, Sahel, the Mediterranean region, southern Africa, and parts of southern Asia, precipitation has decreased. Globally, the area affected by drought has likely increased since the 1970s (IPCC 2007). While there is little research on extreme temperature patterns, there has been an increase in the global mean surface air temperature of about 0.5 °C since the start of the twentieth century, and this is linked to a rise in the minimum daily temperature (Easterling and Wehner 2009). Consistent with this is the trend that in many parts of the world, including Australia, China, Europe, New Zealand, and the United States, there are fewer days with frost. However, this increase in minimum temperature may be due just to a change in the vertical mixing of heat near the surface at night rather than heating (Zhou et al. 2012; McNider 2007).

1.01.2 Extreme Weather Event Effects on Human Health

Extreme weather events such as flooding, drought, and hurricanes can have direct and indirect effects on human health. Effects such as adverse physical health outcomes are related directly to weather, for example, drowning and injuries in floods, injuries and deaths caused by falling debris from structures as they are destroyed by tornados, or increased morbidity and mortality during heat waves or cold snaps. Indirect effects include outcomes related to extreme weather and involve not only physical health outcomes, for example, vector-, food-, and water borne diseases, but also mental health stress or illness, loss of income, compromised nutrition, and social disruption. Infrastructure may be damaged, and so sanitation and access to clean safe drinking water is compromised. The existing infrastructure may not be able to cope with excessive demands during particularly high rainfall events; studies have shown that extreme wet weather events are responsible for a large number of waterborne disease outbreaks in the United States (Curriero et al. 2001).

Displacement of people and permanent migration from flooded areas or areas devastated by droughts are a serious concern, especially for those in rural areas reliant on crops for their livelihood or for those who cannot afford or do not have the means to relocate successfully, for example, those who do not have insurance to fund relocation or those without the necessary education/skills to find work elsewhere. Uncertainty surrounding climate can place mental and economic strain on people, again particularly affecting groups such as farmers whose crop production is dependent on a particular climate for success. Certain groups and individuals within communities will be more vulnerable to extreme weather event effects on their health and well-being, thus differences exist not only because of the nature of the weather event but also because of the population or area that is affected.

1.01.3 At-Risk Populations

Developing nations, urban populations, communities with lower socioeconomic status, and certain individuals, such as the young, a growing aging population, the mentally ill, those with existing medical conditions, and the homeless, are likely to be more vulnerable to negative effects of extreme weather events. Assessing vulnerability is difficult, because, as the United Nations Development Program (UNDP) states: "The social and economic processes that produce vulnerability and contribute to disaster risk are complex" (UNDP 2004). Climate variability and any associated increase in the frequency and magnitude of extreme weather events would exacerbate the problems already faced by developing countries and could undermine the progress of development already made.

Underdeveloped countries have an unequivocal burden of disaster-related mortality – although only 11% of people exposed to natural disasters live in developing countries, they account for 53% of disaster-related deaths (UNDP 2004). Most of the 48 least developed countries (LDCs) are in Africa (33 nations) and Asia (14 nations), whose collective populations comprise more than 880 million people, approximately 12% of the world population. The identification of LDCs is based on three criteria: per capita gross national income, human assets, and economic vulnerability to external shocks (UN http://www.unohrlls.org/en/ldc/25/). The LDC criterion also excludes large economies with populations exceeding 75 million. However, although India is not on this list of LDCs because of its estimated population of 1.17 billion, it is commonly acknowledged to be a developing country. Despite having the world's 12th largest economy, more than half of India's population depend on agriculture for their livelihood and 700 million Indians live on $2 per day or less. Inadequate infrastructure and health care systems in these nations may leave the people unable to cope with and respond to extreme weather events. Many of these developing countries rely heavily on subsistence agriculture (Reed 1997), and so extreme weather events such as drought and increased precipitation will have a larger impact, potentially resulting in famine and widespread mortality.

The urban population (3.42 billion) had surpassed the number of people living in rural areas (3.41 billion) by 2009, and this rapid growth is expected to continue in the next few decades, especially in Africa and Asia where the urban population is expected to double between 2000 and 2030. However, there is a disproportionate number of urban dwellers in developed as opposed to underdeveloped countries (UNFPA 2011; UNDP 2010). Urbanization started in today's more developed regions, and urbanization levels remain high in the more developed nations. For example, in 2009, Australia, New Zealand, and Northern America had urbanization levels grater than 80%. By 2050, Australia, New Zealand, and Northern America are all expected to be over 90% urban, whereas Europe's level of urbanization is projected to be lower, at 84% (UNDP 2010). Because wind velocities are generally lower in urban cities than in open areas, air temperature and mean radiation temperature are often higher, and thus urban populations may be more exposed to higher temperatures than rural populations. Hughes and Balling (1996) have shown that at least half of long-term warming in South Africa in the past 30 years is due to urbanization and that the diurnal temperature range was decreasing in urban areas. Urban dwellers are reliant on centralized water and power supplies, sanitation, and health care systems, and so they are particularly at risk when extreme weather events compromise infrastructure integrity.

Children are more vulnerable to negative effects of extreme weather events compared to adults for several reasons, including small body size, lower body strength, underdeveloped immune system, and lower ability for fast cognitive thinking in emergency situations. Children are more susceptible than adults to air pollutants as they have narrow airways and underdeveloped respiratory systems. When they are playing outside, exercise increases breathing through the mouth, bypassing the filtering of the nose and so pollutants directly enter the lungs.

Older people and children are more vulnerable to the effects of temperature extremes and have a significantly higher mortality risk in extreme weather events. The elderly (65 years and older) accounted for 72% of all heat-related deaths due to the mid-July 1995 heat wave in Chicago, USA (Whitman et al. 1997). Infants lose body heat more easily than adults; in addition, infants cannot make enough body heat by shivering. Children are more prone to develop hypothermia (lowered body temperature) when the body's rate of heat loss is greater than the rate of heat production. Children also have a relatively larger body surface area that contributes to more rapid heat loss. They have smaller bodies with less muscle mass and tone than adults, which make them more vulnerable to drowning in floods. They rehydrate less efficiently than adults and so are more likely to dehydrate under drought conditions or when there is a lack of drinking water, such as when infrastructure is compromised because of extreme events such as flooding, hurricanes, and storms. Children's immune systems are less developed than those of adults, and so they may not be able to fight off infectious diseases, which are more likely when there is lack of potable water or sanitation or when many people are packed in temporary shelters.

Societal effects and preexisting conditions compound negative health effects of extreme weather events on the elderly, so they are more likely to suffer negative health effects from climate stress and vector-borne diseases (Rey et al. 2007; Geller and Zenick 2005; Haq et al. 2008). People who are poorer, have no education, have less access to transportation, and are more disconnected socially will be at greater risk for negative outcomes in natural disasters (Son et al. 2012; Haq et al. 2008). Susceptibility to heat may be increased for the elderly, female, and unmarried, with additional risk factors being preexisting health conditions such as chronic pulmonary disease, diabetes, psychiatric disorders, and pulmonary and cardiovascular conditions (Schifano et al. 2009; Bouchama 2004); however, these differences in susceptibility factors are not universal, and therefore risk factors need to be identified at the local level in order to manage and prevent morbidity and mortality from heat in these groups.

Older people are also more likely to die as a result of hurricanes. Hurricane Katrina was the deadliest hurricane to make landfall in the United States since 1928, with approximately 1000 deaths directly attributed to it. The risk of death from Katrina, in which drowning was the most common cause of death, increased with age – older people were more affected (Brunkard et al. 2008; Jonkman et al. 2009). This is not surprising, given that many elderly people have restricted physical mobility, may lack personal transportation, and may have underlying conditions that predispose them to indirect effects of stress and shock. This was the case in Hurricane Andrew, wherein the elderly had higher mortality because of indirect causes (Combs et al. 1996). Evacuating elderly people with medical conditions can pose a risk in itself. Housing them in local shelters is also potentially risky because of crowded conditions, reduced sanitation, and lack of supplies. Evacuee shelters and emergency medical care centers may not be equipped to care for and treat those with disabilities or chronic diseases. Vulnerabilities of the elderly are complex, because of confounding factors such as race, education, gender, and so on, and also because they may have disabilities or chronic health conditions. For example, generally, the elderly living in coastal areas vulnerable to hurricanes or flooding are at higher risk than those living inland; however, wealth may mollify their vulnerability. For example, wealthy elderly living in Florida barrier islands were found to be less socially vulnerable despite the high risk owing to their location, whereas those living inland, while having lower physical risk, were more likely poorer, which increased their overall risk (Wang and Yarnal 2012).

Vulnerability to disaster is difficult to measure as it is very complex, especially so are the effects on mental health. Although studies have shown that factors such as socioeconomic status, age, and displacement affect vulnerability to mental health disorders as a result of extreme weather events, there are disparities in the data. Kessler et al. (2008) found that mental health outcomes from Hurricane Katrina were only weakly related to sociodemographic factors, indicating a widespread effect of this hurricane even 2 years after the event. Perhaps in such an extensive massive disaster (Katrina devastated an area equivalent to the size of Great Britain), all people, not just high-risk groups, will be vulnerable.

To mitigate vulnerability to extreme weather events, vulnerable nations, communities, and individuals first need to be identified. However, there are inherent scientific, social, and political problems associated with coming up with such lists. An individual's vulnerability to extreme weather events is complex and dependent on a number of interacting factors. Institutions vested in protecting human health must make decisions regarding where to place their efforts and resources. Funds and resources available to address extreme weather preparedness and response are limited and so must be targeted toward those most at risk.

1.01.4 Temperature Extremes

1.01.4.1 Heat Waves and Droughts

Heat is associated with increased morbidity and mortality, especially among the elderly (Hajat et al. 2002; Pattenden et al. 2003; Rey et al. 2007). Defining what constitutes a 'hot day' or a 'heat wave' is difficult because climate, and thus acclimatization, varies with location. A hot day occurs when the temperature exceeds the 90th–95th percentile of the local daily temperature (IPCC 2007; Jones et al. 1999; Pan and Zhai 2002; Yan et al. 2002; Hua et al. 2006; Fang et al. 2008). A heat wave is generally defined to be when hot days persist for more than 2–5 days. The frequency of extremely hot days in temperate zones doubles for every 2–3 °C rise in temperature during an average summer (Bunyavanich et al. 2003). Prolonged exposure to high temperatures can cause heat cramps, heat exhaustion, and heat stroke. Symptoms of heat exhaustion include heavy sweating, nausea, lightheadedness, and feeling faint. Symptoms of heat stroke include a body temperature of 40 °C (104 °F) or more; lack of sweating, nausea, and vomiting; flushed skin; rapid breathing; racing heartbeat; headache; confusion; unconsciousness; and muscle cramps or weakness. People most vulnerable to heat wave-associated mortality include the elderly, women, and those with certain conditions such as respiratory system diseases, nervous system diseases, mental disorders, infectious diseases, and endocrine and nutritional diseases (Rey et al. 2007).

There is an apparent trend toward increasing hot days and heat waves in recent years. Ding et al. (2010) investigated hot days and heat waves in China during 1961–2007 and found an increasing trend of hot days after the 1990s in all regions of that country. However, there are regional differences; for example, hot days and heat waves most frequently occur in northwestern and southeastern China. These spatial differences highlight the problem that these extreme weather events typically affect smaller areas but to a great extent and thus the health, societal, and economic burdens may be carried by a local area. A record-breaking heat wave occurred in Europe in the summer of 2003, with temperatures more than 3 °C above the average level of 1961–90, which resulted in widespread droughts, crop losses, and more than 22 000 heat-related deaths across Europe (Christoph and Gerd 2004; Levinson and Waple 2004; Rey et al. 2007). This heat wave was found to be due to a stagnant high pressure region over the area whose effect was magnified by a drier-than-average land surface (Chase et al. 2006, 2008; Connolley 2008). The Moscow heat wave of 2010 was analyzed by Dole et al. (2011) who concluded that this heat wave was mainly because of internal atmospheric dynamical processes that produced and maintained a strong and long-lived blocking event and that similar atmospheric patterns have occurred with prior heat waves in this region.

The Chicago heat wave, occurring between 12 July and 16 July 1995, was the cause of almost 700 deaths. Temperatures ranged between 93 °F and 104 °F, with the highest temperature recorded on July 13, with a heat index of 119 °F (Donoghue et al. 1995). The event affected predominantly high-risk populations, such as low-income and uneducated families, people with preexisting medical conditions, and people who were constrained to bed with need for assistance from visiting medical care. Previous studies have demonstrated that the main factors leading to death during heat wave are cardiovascular diseases (Kilbourne et al. 1982). A study investigating the cause-specific mortalities over a 50-day period in the Chicago area (with midpoint around the occurrence of the heat wave) confirmed that sudden death and cardiovascular causes were recorded as the predominant reason for deaths on most death certificates (Kaiser et al. 2007). The same research also confirmed that poor less-educated populations were highly affected by the heat wave. Some of the families included people in urban areas with no previous education on protective measures against extreme weather events as well as poor living conditions without any cooling system, such as air-conditioners or fans. Such extreme weather events confirm that socioeconomic status could play a crucial role in determining the likelihood of survival among different populations.

More than half of all deaths associated with natural hazards are drought related, and drought is second only to floods in terms of the number of people affected (Below et al. 2007). Droughts can also have secondary impacts such as reduced water availability, wildfire danger, and destruction of agricultural crops (and hence reduced food availability). Droughts are also difficult to define. Media reports can be misleading especially since droughts can be very localized and thus have major effects on small areas that may be perceived to be more widespread than they actually are. One example is the drought of 2002 in Colorado, USA. the onset of drought in 2002, the preceeding years showed below-average snowfall and higher temperatures during the winter seasons. In 2000, drought contributed to severe wildfires during the summer months. The low precipitation during the years preceding 2002 brought depletion of soil moisture and surface water supplies because of high evaporation rates as a result of higher-than-average temperatures (Doesken and Pielke Sr 2008; Pielke et al. 2005). During the spring months of 2002, the usual spring storms for the area did not occur and temperatures rose to record high levels. Wildfires, water depletion, and crop deterioration were the outcome of the drought, as well as massive die-off of dominant tree species in an area spanning approximately 12 000 km^2 (Breshears et al. 2005). Implications associated with reduction of forest mass bring along ecological consequences, such as carbon emissions, further temperatures rises, soil erosion, and loss of ecosystem previously supported by trees (Luo 2007; Breshears and Allen 2002). The 2011 heat wave in Russia fueled disastrous wildfires and killed nearly 56 000 people as result of heat and increased air pollution and destroyed one-third of the country's wheat crop. Heat waves and drought not only cause death, particularly of more susceptible people such as the very young and the elderly, but also can have wide-ranging devastating effects on food sources.

1.01.4.2 Extreme Cold

Severe cold is a weather pattern that can have deleterious effects on an impacted region and accounts for high levels of mortality during the winter months in the temperate regions of the planet. Exposure to extremely low temperatures presents high health risk to vulnerable populations such as children, elderly, homeless, intoxicated people, and those with preexisting health conditions, such as ischemic heart disease. In addition, severe cold could impact the economy of a region by immobilization because of heavy snowfall or could affect energy demands, production, agriculture, and livestock. It has been estimated that severe cold accounts for 3–18% of the total annual mortality in economically developed countries during the winter months (Sakamoto-Momiyama 1977; Rosenwaike 1966; Curwen 1990). Records collected for the years 1979 through 2002 indicate that extreme cold is the number one cause of deaths due to weather-related events in the United States, outnumbering other weather extremes such as hurricanes, extreme heat, floods, droughts, tornados, and lightening (Goklany 2007). In the United States, it is estimated that the annual deaths related to extreme cold are 0.8% of the average annual deaths (Deschenes and Moretti 2007).

Typically, severe cold events are followed by an increase in coronary heart disease mortality, cerebrovascular accidents, and respiratory diseases. The normal deep core body temperature is generally maintained at a steady 37 °C (Lloyd 1994). Heat is generated through the body's normal metabolism, and temperature is maintained at a steady value by the thermostatic mechanism in the hypothalamus (Clark et al. 1939). Metabolic or environmental factors can influence body temperature, and beyond certain limits the body experiences either heat stroke or hypothermia. When body temperature begins to drop, superficial and limb blood vessels constrict, thus conserving heat by reducing the difference between skin and environmental temperatures. If the core temperature falls below 35 °C and the rate of heat loss from the body exceeds the rate at which the body is producing heat, individuals are considered to be experiencing hypothermia (Danzl and Pozos 1994; Duguid et al. 1961; Larach 1995; Lloyd 1994). Below 35 °C, physiologic responses to reduce heat loss through radiation, conduction, convection, respiration, and evaporation are very limited because of the failure of the coordinated system to achieve thermoregulation (Hanania and Zimmerman 1999; Mills 1980; Paton 1983).

Hypothermia has four subdivisions: mild, 32–35 °C; moderate, 28–32 °C; severe, 20–28 °C; and profound, at less than 20 °C (Jolly and Ghezzi 1992). During cold months, cases related to hypothermia increase and deleterious effects from it can spread to multiple organ systems, such as renal, cardiac, and central nervous systems (Herity et al. 1991; Ulrich and Rathlev 2004). Heart-related deaths due to severe cold are a result of rising blood pressure because of cold temperatures and an increased chance of blood clots because of the rise of protein levels in the blood. Moreover, as a result of cold temperatures, oxygen supplies to the heart can be reduced due to restricted blood flow from coronary artery spasms (Nabel et al. 1988). Severe cold can have deleterious effect on people with ischemic heart disease, which is characterized by reduced blood supply to the heart. For example, in England and Wales, mortality is 50% higher in winter than in summer and deaths related to ischemic heart disease increase by 20 000 in winter months (Rose 1966; Pell and Cobbe 1999). Extremes such as blizzards during the winter months can drastically increase mortality rates among people with ischemic heart disease. A study conducted in eastern Massachusetts examining death certificates after six blizzards in 1974–78 reported that after a 'blizzard week,' mortality was 8% higher than in preceding (control) weeks. In addition, deaths from ischemic heart disease accounted for 90% of the excess deaths for the same weeks (Glass and Zack 1979).

The risk of upper and lower respiratory tract infections also peaks during the winter season (Mourtzoukou and Falagas 2007; Eccles 2002; Mäkinen et al. 2009). Most studies suggest that susceptibility to infection could be related to suppressed immune responses from vasoconstriction in the respiratory tract mucosa because of lower core body temperature from inhaled cold air and cooling of the body surface. Other studies suggest that indoor crowding during the winter months promotes transmission of pathogens. Further studies propose that seasonal exposure to cold air causes an increase in the incidence of upper respiratory tract infections due to cooling of the nasal airway (Eccles 2002).

Shelter, heating, and warm clothes are typical ways to avoid morbidity and mortality due to cold weather extremes. Those who are in lower socioeconomic groups are more likely to suffer from extreme cold because they lack these essentials. People who are acclimatized to cold temperatures by living in areas that commonly experience cold weather will not only be better able to cope physiologically with cold extremes but also typically have adequate heating systems and protective clothing readily available.

1.01.5 Extreme Precipitation Events

1.01.5.1 Extreme Rainfall and Flooding

A flood is an overflow of a huge amount of water that submerges normally dry land. There are several types of floods: riverine floods caused by excessively heavy rains on to rivers or other types of waterways, estuarine floods caused by sea tidal surges and storm winds, and coastal floods caused by natural disasters including typhoons, high tides, wind storms, and tsunamis (Rappaport 2000). Floods are one of the most common natural disasters, and each year they cause an enormous amount of damage all over the globe. Moreover, floods are one of the leading causes of death each year compared to other natural disasters, accounting for an estimated 40% of all natural disasters (Howard et al. 1996). An estimated total of 1816 worldwide freshwater floods (e.g., river floods, flash floods (damaged dams), or drainage floods) affected more than 2.2 billion persons between 1975 and 2002, and the death toll was over 17 500 (Jonkman 2005). The same study showed that Asia topped the list with the highest amount of impacts from river floods. In the summer of 2010, one-fifth of Pakistan was under water. Over 20 million people were affected by flooding that ran the length of the country along the Indus River, destroyed more than 1.6 million acres of crops, and resulted in millions becoming homeless.

The economic loss from floods is also very high. Impaired infrastructure as a result of floods includes damage or collapse of health center, office, and residential buildings and damage to bridges, roads, and railroads. Floods can greatly impair agricultural production and supply by submerging and killing crops, spoiling produce, removing topsoil from farmlands, and affecting future cultivation.

Multiple environmental consequences can result after flooding from the spread of waterborne pathogens and infectious diseases. In the event of flooding, there is a high risk of damages to water purification and sewage disposal systems. Access to adequate water supplies could be limited because of contamination from fecal materials or dislodgement of toxic chemicals (Wilder-Smith 2005). Open wounds could be easily infected with opportunistic skin pathogens and freshwater- or seawater-borne pathogens.

Coastal floods contribute to the highest mortality after windstorm events including hurricanes, cyclones, and typhoons (Rappaport 2000). Storms like these are characterized by severe flood effects and often appear without warning, with little time for evacuation. Densely populated coastal countries, such as Bangladesh, have been severely impacted over the past decade because of its geographical setting (in the path of tropical cyclones), wide and shallow continental shelf, and the funneling shape of the coast (Karim and Mimura 2008; Das 1972; Murty et al. 1986). Cyclones in 1970 and 1991 have caused at least 500 000 and 138 000 deaths, respectively (Haque 1997; Karim and Mimura 2008). Similar cyclones in later years have resulted in fewer deaths in Bangladesh because of improved evacuation plans. However, countries such as Bangladesh more recently are experiencing different types of flood disasters, namely, floods from ever-rising sea levels because of global warming (Karim and Mimura 2008; Bhuiyan and Dutta 2012; Khan et al. 2011).

1.01.5.2 Tropical Cyclones

Hurricanes and hurricane surges are among the most devastating weather-related effects for coastal areas. The effects of a hurricane could cost billions of dollars in damage to local communities, and the death toll may possibly be overwhelming. Hurricanes usually form in late summer and early fall over warm tropical waters. They are a type of tropical cyclone (a low-pressure system forming in the tropics) with intense spiraling storm winds reaching speeds equal to or above 33 $\mathrm{m\ s^{-1}}$ (64 kt, 74 mph). There are several precursors to the formation of a hurricane: warm ocean waters (26.5 °C [80 °F]), humidity, weak vertical wind shear (shear is the movement of one layer of air over another), easterly waves (large areas of low-pressure air), convection, and thunderstorm activity. Hurricanes are fueled by the rise of warm humid air that later condenses to form clouds and rain. The heat, previously trapped in the water vapor, is released, and under the right conditions, a low-pressure system forms, causing wind to spiral inward (Lauber 1996). The devastating consequences of hurricanes could affect millions of residents, although the most vulnerable are the economically disadvantaged, such as elderly, children, pregnant women, parents, mentally ill, or those with preexisting medical conditions. An aftermath of a hurricane could be mortalities, permanent home displacement, injuries, poor hygiene, malnutrition, lack of access to safe water supplies, infections, scarce food sources, and psychological damages such as posttraumatic stress disorder (PTSD), posttraumatic stress symptoms (PTSS), major depressive disorders (MDD), or generalized anxiety disorder symptoms (GAD).

Hurricanes in the Atlantic have dramatically increased during the past decade and have caused more than $150 billion in damages in 2004 and 2005 (Pielke et al. 2008). The most costly and devastating hurricane to local residents was Hurricane Katrina that made landfall on the US Gulf Coast on 29 August 2005, destroying the city of New Orleans, LA, USA. The hurricane left behind immense damage, human fatalities, injuries, permanent home displacement, and mental distress to most of the local residents. In addition, the aftermath caused disruption in the supply of fresh water, insufficient access to safe food, direct exposure to environmental toxins, spread of infectious diseases, and lack of accessible medical care because of the destruction of infrastructure and medical centers. The death toll was estimated to be 1577 in Louisiana (Sharkey 2007), but the number is still a matter of controversy, because it is still unclear what was directly and indirectly affected by the hurricane.

The most vulnerable victims were pregnant women, children, elderly, low-income residents, and those with preexisting health conditions. Lack of information about preparedness, evacuation, and adequate transportation is a limiting factor for low-income families. A survey conducted at one of the shelters concluded that some of the residences never heard the evacuation order or did not understand the instructions; others who did hear the order did not have a car or other means for evacuation (Brodie et al. 2006). The same survey reported that 54% had no health insurance before the hurricane and 72% did not have insurance to cover their destroyed homes. In addition, 41% of the shelter residents did not evacuate because of preexisting health conditions, such as heart disease, hypertension, diabetes, or asthma. A large portion of the evacuees were low-income families with no health insurance, who relied on the New Orleans public hospital system for their medical needs before the hurricane, and this facility was destroyed in the storm (Brodie et al. 2006). Patients undergoing hemodialysis were also affected in the aftermath of the hurricane; 44.0% of participants in a study reported missing at least one hemodialysis session after the hurricane, and 16.8% reported missing three or more sessions (Anderson et al. 2009). Mental distress and PTSD were detected at high levels among residents of New Orleans and surrounding areas after the hurricane, compared to prehurricane levels. A study conducted of displaced groups 6–12 months post-Katrina and again 20–23 months later reported that mental distress levels did not decline between the two surveys (Abramson et al. 2008). Furthermore, traumas such as PTSD could leave long-lasting damages to those affected. A study assessing the effects of PTSD on young females (fourth to eighth grades) concluded that symptoms of PTSD not only persisted during the 2.5-year period but also increased with time (Weems et al. 2010). The psychological stress that was experienced during natural disasters reflects on also pregnant women with otherwise healthy pregnancies. Poor pregnancy in women with PTSD was observed in the aftermath of the Hurricane Katrina. For example, pregnant women exposed to the hurricane had low-birth-weight infants compared to those not exposed (Xiong et al. 2008).

Other effects of hurricanes, particularly to coastal inhabitants, are floods and the spread of infectious diseases. Such a scenario developed in 1998 when Hurricane Mitch hit Honduras, Guatemala, and Nicaragua and brought about 11 000 deaths. Acute respiratory infections (ARI) and acute diarrheas (AD) claimed a large portion of the lives (Campanella 1999). Comparison with predisaster data in Nicaragua showed that 6798 of 100 000 inhabitants were affected by AD compared to 2849 before the impact and that 1205 versus 295 of 100 000 inhabitants were affected by ARI (Campanella 1999). In addition, it was estimated that 58% of the 1998 maize crop and 6% of the bean crop were destroyed in the aftermath of Hurricane Mitch in Honduras (ECLAC 1999). These crops were the main source of income for many of the impacted residents. Furthermore, as a consequence of the floods after the hurricane, elevated levels of chlorinated and organophosphate pesticides were detected in adolescents (Balluz et al. 2001).

1.01.6 Extreme Wind Events

1.01.6.1 Dust Storms

Dust storms are one of the main contributors to a global rise of allergic reactions, asthma attacks, chronic breathing, lung problems, as well as cardiovascular and heart diseases. It has been estimated that the annual quantity of desert dust that makes regional or global airborne migrations is 0.5–5.0 billion tons (Perkins 2001). Dust storm refers to fine grain particles or sand dust picked up by strong wind forces and suspended in subsurface airflow for a long time. The event happens when wind forces surpass a given threshold level that acts on fine land particles, and as a result they are no longer held in the surface by their own weight and interparticle bonding (Squires 2007). Dust storms form mainly as a consequence of soil erosion by windstorms in drylands such as arid or semiarid regions, generally in subtropical latitudes.

Factors influencing the formation of dust storms include natural and anthropogenic forces. Extremely dry places throughout the globe, such as deserts, are the main cause of suspended dust in the air. Dust storms formed in the desert can travel long distances and affect areas that are not naturally arid, causing allergic reactions and asthma attacks in the local populations. Mattson and Nilsen (1996) point to the Sahara region in Africa as the main contributor of dust storms in the planet, affecting distant regions, such as Europe and the Americas, on a regular basis. Other arid places dispersing fine dust particles across oceans are the Sahel regions of North Africa and the Gobi and Takla Makan regions of Asia.

Dust storms from the Sahara are transported to the Americas over the Atlantic by tropical eastern winds. Some of the highest number of asthma casualties are in the Caribbean islands and are linked to African dust storms (Monteil et al. 2000). In the island of Barbados, for example, there has been a 17-fold increase of patients with asthma since 1973, which correlates with the onset of drought in Northern Africa in 1970 (Howitt 2000). Other symptoms recorded after dust events in the Caribbean islands include sinus stress, migraine headache, eye irritation, and chest pain. Another research demonstrates a link between concentrations of African dust and respiratory stress in the Caribbean island of Trinidad (Gyan et al. 2005).

Desertification caused by human activities and climate is another factor that opens new arid territories and grounds for the formation of dust storms. In China, for example, between 1975 and 1987, the desertification rate was approximately 2100 km^2 year^{-1} (Zhenda and Tao 1993). Many people suffer from sore throat and asthma after a dust storm in China. Owing to the low air quality and high concentration of pollutants in the air above China, dust storms are often mixed with heavy metals or airborne pathogenic microorganisms.

Severe drought in combination with poor land use is another factor that contributes to the formation of dust storms.

One of the most famous examples is the Dust Bow drought of 1930 in North America during which severe dust storms covered 75% of North America. The event began with the expansion of agricultural land during the 1920s. Much of the native drought-resistant grass in the Great Plains was replaced by wheat crops. With the onset of the drought in 1930s, much of the crop fields became devastated, exposing bare land to the forces of the wind (Cook et al. 2008, 2009). The dust storm reflected harshly on the health and socioeconomic state of the affected residents of the Plains. Many local people suffered what is known as 'dust pneumonia' – clogging of the lungs with dust, causing severe allergic reactions and the consequent death of thousands. The Dust Bowl also brought many people to poverty, lowering their health standards and forcing them to move to new areas leaving everything behind.

Dust storms are also transporters of microorganisms, some of which are highly pathogenic to humans. Microorganisms are natural inhabitants of top surface soils and sands and include bacteria, fungi, fungal spores, and viruses. During dust storms, they are easily picked up and carried along with the rest of the components in the storm (Griffin 2007). It is believed that dust particles cause abrasion to the nasopharyngeal mucosa in humans and thus promote microbial infections on inhalation (Molesworth et al. 2002). For example, outbreaks of meningitis due to *Neisseria meningitidis* infection are linked to dust storms that are common events during the dry season in North Africa (Sultan et al. 2005). In another research conducted in Mali, 25% of detected microorganisms during a dust storm were human pathogens (Kellogg et al. 2004). The fungal pathogen *Coccidioides immitis,* which causes coccidioidomycosis outbreaks, has been associated with dust storms. An outbreak of coccidioidomycosis was documented after a dust storm in a Naval Air Station in California (Williams et al. 1979).

1.01.6.2 Tornadoes

Tornadoes are natural disasters that are responsible for part of the world death toll each year. The enormous damage that tornadoes usually leave behind affects many aspects of the public health and economic stability of a region or a country. The most prevalent health impact that tornadoes cause are injuries from flying debris, fractures, head injuries, cervical spine trauma, psychological trauma, wound infections, lower hygiene due to home displacement, or outbreaks of infectious diseases. Tornadoes can form anywhere in the world and so far have been detected in every continent except Antarctica. However, the highest frequency of tornado incidences is in North America in the so-called Tornado Alley region of the United States. A tornado is defined as a violently rotating column of air extending from a thunderstorm to the surface of the Earth. The prerequisites for tornado formation are thunderstorm, moisture to feed thunderstorms, and temperature instabilities that are usually associated with spring and summer warming. Most tornadoes happen in agricultural areas where moisture is plentiful.

Tornadoes continue to cause loss of life in the United States (**Figure 2**), however, fatality rates have been well below 1:1 000 000 since 1975 (Brooks and Doswell 2002); despite this, there is a potential for considerable loss of property, subsistence, and life. While the 'Tornado Alley' region of North America has the highest tornado incidence, maximum of fatalities occur in the Deep South and this is likely due to differences in vulnerabilities of the areas' populations and perceptions of immediate danger (Ashley 2007).

The most immediate threat of tornadoes to humans is instant death. On average, the death toll varies from country to country and from year to year, but in general, densely populated areas prone to the formation of tornadoes, such as Bangladesh, have the highest mortality incidents (Finch 2008). Other threats such as injuries from flying debris are often associated with open wound infection. One such example was the outbreak among victims of unusual cutaneous mucormycosis or fatal necrotizing fungal soft-tissue infection due to mucormycete *Apophysomyces trapeziformis* several days after a tornado had struck Joplin, Missouri (USA) on 22 May 2011 (Center for Disease Control and Prevention 2011). This disease exhibits fatality rates between 29% and

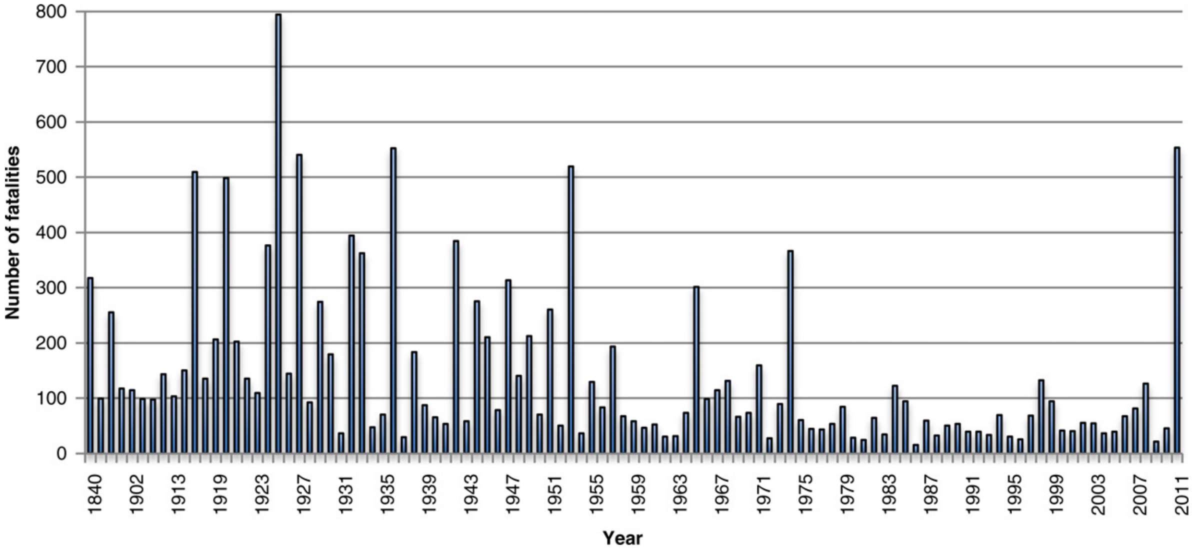

Figure 2 Fatalities attributed to tornadoes in the United States (1840–2011).

83% (Alvarez et al. 2010). Victims living through tornadoes can experience mental health-related complications or PTSD, which often affect them for life. The standard of life of such victims is immediately lowered because of their inability to return to work, or in the case of farmers, losing subsistence altogether.

Specific socioeconomic groups are extremely vulnerable to the aftereffects of tornado disasters. Among them are elderly, children, immigrants, those with preexisting health conditions, mentally ill, poor, or uneducated individuals. These groups are less likely to act adequately to an approaching disaster because of their limited access to receive and interpret forecasts or warnings. Poor groups are more likely to be affected by tornadoes disproportionately because of their economic disadvantage to purchase supplies, to secure better home structure, or to build a shelter. Mobile homes, often afforded by low-income groups, have light structures and frequently cannot withstand the wind forces associated with a tornado. It has been estimated that there is 10–15 times greater chance of fatalities due to tornadoes in mobile homes than there is in a permanent structure (Brooks and Doswell 2002; Simmons and Sutter 2006). For example, 43.2% (536 of 1240) of US tornado fatalities, between 1985 and 2007, occurred in mobile homes (Sutter and Simmons 2010). Sutter and Simons (2010) disclosed that less-powerful tornadoes on Enhanced Fujita Scale (EF1, EF2, or EF3) can bring just as much mobile home fatalities as the ones with a scale EF4 and EF5. Furthermore, the poor and less educated are less likely to have a reliable access to a warning system and thus less likely to comply in a timely manner. In addition, lack of reliable means of transportation before and after a disaster can exacerbate significantly the cause and effect of a tornado or hamper access to disaster assistance centers.

The disadvantage in an event of a tornado is often associated with a limited advance warning system. The elderly are greatly endangered because of that, since their impaired cognitive abilities and decreased sensory awareness to interpret warning systems limits their adequate response (Daley et al. 2005). They have been found to be the second most at-risk population after mobile home residents because of their compromised mobility and slower evacuation effort (Ablah et al. 2007). People with preexisting medical conditions, inside or outside medical facilities, are also extremely vulnerable to tornadoes, because their need for assistance could severely impact their effort for survival. Mental disorders too are likely to peak after tornados because of agitation, anxiety, and stress that affect survivors.

Hospitals are extremely vulnerable to the destructive forces of a tornado because many patients are dependent on medical equipment run by electricity. For example, one of the strongest tornadoes ever recorded in the United States occurred in Joplin, MO (on May 22, 2011) and devastated one of the city's major hospitals – St. John's Regional Medical Center. The hospital was left without power, and five people died during the night of the aftermath, despite the effort of the medical personnel to save their lives (SoRelle 2011). Hospitals are sometimes the only medical facility in some of the rural regions in United States, and if their structure and power are damaged by the indiscriminative path of a tornado, little help could be provided to the heavily injured or those already on hospital medical assistance.

Improved warning systems over the past 50 years have significantly decreased tornado-related fatalities. It has been estimated that the fatality rate dropped from 1.8 per million impacted residents to 0.11 per million (Sutter and Simmons 2010). Local, state, and federal educational programs can greatly reduce the number of fatalities attributed to tornadoes. The diverse levels of vulnerability and at-risk populations should be taken into consideration when educational approaches for disaster preparedness are being developed (Kusenbach et al. 2010). Different stressors should be applied when educational programs are being administered. For example, preparedness kits are often recommended to be kept in a sheltered area or a safe room. This does not apply to mobile home residents as they never should seek shelter in their own homes (Kusenbach et al. 2010). However, warning systems are ineffective if there is lack of underground disaster shelters or house basements. As it was the case in Joplin, MO, USA, nearly 78% of houses in the area lacked basements, owing to the area's rocky ground and high water table (Joplin Globe, 2011). One solution to that problem could be the construction of community shelters that could withstand the force winds associated with tornadoes. Other alternatives can include the construction of an in-house safe room with subsidies provided by FEMA or financial incentives from other public authorities.

1.01.7 Health Care Infrastructure and Emergency Preparedness

1.01.7.1 Risk Concepts – Risk Reduction and Management

Risk management is aimed at reducing losses to extreme weather-related disasters. As previously mentioned, developing countries are at a greater risk for negative effects of extreme weather events. Impoverishment and lack of local resources, governance, and infrastructure often contribute to a community's vulnerability. Natural disasters can reverse years and even decades of development work, and risk management needs to be implemented to reduce the vulnerability to these hazards. The first step in risk reduction and management is risk identification and assessment. While larger operatives, for example, government agencies, may assess risk based on predicted future scenarios, community risk assessment operates more at a local immediate level and is based on current coping capacities, from which extrapolations are made regarding future risk.

As discussed earlier, communities, countries, or regions differ greatly in vulnerability, and hence in the effects they may suffer from extreme weather events. Risk reduction will need to occur at various scales from educating a vulnerable population to global reduction of greenhouse gas emissions. It also will work at different political scales, from city governments to global networks such as the United Nations. Risk reduction will also need to involve a cross-sector multidisciplinary approach. Partnerships need to be developed between such different agencies as meteorological and health offices. On multinational, national, or regional scales, policies and regulatory measures must be developed and implemented to accomplish vulnerability reduction. For example, regulations controlling land use and housing structure quality can be enforced by public agencies. Development of infrastructure will play a large part in reducing vulnerability and ensuring development sustainability. While mitigating anthropogenic climate effects could result in far-reaching reductions of weather uncertainty and damage to natural resources and large-scale infrastructure, this top-down approach does not address differences in vulnerability to extreme weather events that typically operate at smaller scales.

Many climate extremes occur at smaller spatial scales, and so local authorities must have the building capacity to avoid the negative effects of these. The populace must be enabled to reduce risk at the individual and local level, giving individuals the knowledge, skills, and tools to reduce risk, for example, elderly people having the ability to prevent negative health effects of extreme temperatures via having access to home heating or cooling systems and the homeless having access to community shelters and appropriate clothing. Reduction of individual poverty and increasing livelihood success will enable communities to prepare for extreme weather events and to maintain (and preferably improve) current living standards despite any possible increase in frequency and intensity of extreme weather events.

Community-level action will be imperative in risk reduction at this scale. For example, land use planning and natural resource management, particularly watershed management, play a critical role in reducing risks of extreme weather events such as hurricanes and flooding. Economic losses due to Hurricane Mitch, which largely hit Central America in 1998, were more than $7.5 billion (USAID 1999). Much of these economic losses have been attributed to wide-scale deforestation, inadequate design, and ill-planned siting of housing and infrastructure (e.g., roads and bridges). Preserving forests conserves water resources and prevents flooding. By reducing runoff, forests control erosion and salinity. Consequently, maintaining forest cover can reduce siltation of rivers, protection of fisheries, and investment in hydroelectric power facilities (Chomitz and Kumari 1996). Areas with forest cover suffered fewer landslides than deforested areas, and terracing of deforested steep slopes aided in reducing landslides during extreme rainfall events of Hurricane Mitch (Sivanpillai and Thurow 2008). While Hurricane Mitch was the deadliest hurricane in the Americas since the 'The Great Hurricane' of 1780 and President of Honduras, Carlos Flores Facusse, claimed the storm destroyed 50 years of progress, it is certainly not an anomaly to the region (National Climate Data Center 1999). The Greater Caribbean Region experiences an average of 10 'named' tropical storms per year, of which 6 are classified as hurricanes; however, the activity is not uniform year to year, making predictions difficult (OAS 1991). Climate model scenarios suggest that the frequency and severity of extreme climate events might increase, although globally, tropical cyclone activity is at an all-time low (Maue 2012). For example, three of the last four Atlantic Basin hurricane seasons were exceptionally active. In the past 3 years, there were a total of 32 hurricane force tropical storms. This amounts to an average of eight per year, which is two above the long-term average of six storms a year (USAID 1999). Small underdeveloped nations in the Caribbean need to enable their residents to prepare for tropical storms to minimize their negative effects. There are examples where community-based programs aid greatly in adapting to extreme weather. A local NGO in Kitui, Kenya, has implemented a program to mitigate droughts by community building of 'sand dams,' which are designed such that water is stored in the sand that is kept behind the dam as an artificial aquifer (Lasage et al. 2006). Sand dams provide a close clean water source and have reduced walking distance, thereby increasing the time available for other productive activities.

Developing countries may be more vulnerable to the negative effects of extreme weather, but recent events show that developed countries are also at risk. For example, Typhoon Talas, which hit Japan in early September 2011, killed over 70 people, marking the deadliest tropical cyclone to affect the nation in 7 years. The recent (2011) droughts in Europe resulted in subsidence (affecting structure integrity), reduced crop production (leading not only to reduced food source but also to reduced livestock feed), and threats to power production (nuclear power reactors are water-cooled). Farmers were initially the hardest hit with loss of income because of reduced crop production, and many chose to sell livestock rather than feed them. Farming is inherently an uncertain business, and climate adds to this uncertainty and puts more pressure on this industry. Trickle-down effects included increased food prices, which affects low-income individuals and families the most. Building local food resilience will aid greatly in reducing vulnerability to effects of extreme weather events. People should be educated about and be involved in localized food production, farmers' markets, and gardening and farming projects in schools and by community groups to enhance food sustainability.

Recent floods in Australia highlight the fact that individual education and training are also imperative to preventing and coping with risks associated with extreme weather. In this case, it has been suggested that the dam operators made a suboptimal decision in assuming a no-rainfall scenario for dam discharge, resulting in downstream flooding (van den Honert and McAneney 2011). Challenges to an individualized approach, however, include difficulty in regulating this standardization and quality control maintenance. For example, it is difficult and resource intensive to test and maintain quality control of individual in-home health carers. Individualized approaches tend to be resource intensive and may pose problems when trying to implement these in large regions; however, they also tend to target the more vulnerable groups of a population and so have more of a positive impact.

1.01.7.2 Coping Capacity and Disaster Response

Society most often prepares for and responds to natural disasters using a top-down approach (e.g., national emergency relief institutions). Response decisions are made by governmental agencies, and vulnerable groups may be excluded from this process. Infrastructure designed to protect from such disasters is typically designed for the centers of urban areas. Vulnerable groups are often forced to live on the outskirts of urban areas, which subsequently puts them at higher risk to extreme events such as flooding. Advantages to a top-down approach include the availability of international funds, for example, when a country declares a state of emergency; this

Coping Capacity

Figure 3 Conceptual framework for a bottom-up approach to weather disaster risk management, reduction, and coping capacity.

shifts blame away from lack of preparedness and coping ability to the disaster itself (Schipper and Pelling 2006). However, a bottom-up approach, such as increasing social capital, enables preparedness, coping, and response at the individual and community level and works to equalize empowerment within the community. Social capital can be described as networks of relationships and flows of information within a society. Social capital concepts such as solidarity, social cohesion, social interaction, and social networks will enhance the capacity of individuals, groups, communities, and organizations to ensure social development and ability to cope with and respond to extreme weather events.

Self-help during disasters can be critical in an individual's ability to cope and survive. Health status affects an individual's ability to respond to and cope with disasters. There are gross inequalities in health between countries; for example, life expectancy at birth ranges from 34 years in Sierra Leone to 81.9 years in Japan (WHO 2004). However, there are also gross inequalities in health within countries. For example, in 2007, US county-level life expectancies ranged from 15 years ahead of the international frontier (average life expectancy in the top 10 countries) to over 50 years behind for men and 16 years ahead to over 50 years behind for women (Kulkarni 2011). Health disparities can be related to socioeconomic status and race/ethnicity; however, there are other factors that contribute, such as quality of care and education.

Many hospitals and other health care facilities, including long-term care facilities, operate 'at capacity' under normal daily conditions, and most are not prepared to meet a sudden increased demand for services resulting from an extreme weather event. Confounding this is the possibility that health care structures and services may be damaged or impaired directly as a result of the disaster and health care workers may be injured or killed. Indirect effects of extreme weather events on health systems include roads that may be damaged or compromised (e.g., blocked by debris or traffic of evacuees) limiting ambulance access to afflicted areas or flow of information to affected communities; gas may not be readily available to run ambulances. Adaptive capacity in the health sector is imperative in the ability to cope with and respond to such disasters and is reliant on individual health and prosperity (Figure 3).

Individual health and prosperity leads to higher public expenditure on health and improved human capital, for example, more local clinics and skilled health professionals. It also leads to competent and prepared local community groups, which enables resilience and ability to cope with disasters. Good disaster response management at the local level also maximizes available resources and distributes them within the community where they are most needed. The Red Cross often partners with community groups, such as church communities and community centers, and is often successful at working together and sharing resources to respond to disasters and rebuild afterward. The American Red Cross, working out of local churches and community centers, provided services for people with significant damage from the 2012 tornadoes in

Alabama, USA, meeting one-on-one with caseworkers and health and mental health professionals, offering local resources and referrals, help with prescriptions and other emergency medical needs, and bulk distribution of supplies such as tarps, rakes, shovels, trash bags, gloves, comfort kits of toiletry items and clean-up kits. Enabling local health professionals and citizens allows the community to work together to respond to and cope with extreme weather events, with the added benefit of building a stronger sense of community, which may in turn benefit the more vulnerable groups and individuals within.

1.01.8 Opportunities and Challenges for the Future

There lie ahead several far-reaching challenges to preparing for and coping with the uncertainty surrounding climate and extreme weather events. We have shown that many populations have survived extreme weather events. However, some sectors are more sensitive, and when affected, the gap between groups in their ability to cope and adapt can widen. Rather than blame for effects of disasters being placed on natural hazards, the main causes of disasters are due to human actions and the vulnerabilities of human beings. Focusing on the human aspect rather than the disaster itself will enable more effective risk management and disaster response.

Urbanization may not only lead to less poverty but also to increasing vulnerability due to development, for example, landslides, centralized water, and food supplies. However, rural areas that rely directly on agriculture and fisheries for food and livelihood can be devastated by even localized extreme weather events, and recovery can be lengthy. Increased communication technologies and partnerships will provide a solid framework for the development of risk mitigation and emergency response. Frameworks must be developed for mitigating risk and coping with disasters – linking the health sector to emergency planning groups.

Knowledge gaps exist, including a paucity of quantitative data on activities and health impacts of extreme weather events, on whether extreme weather events can be predicted, and on whether better warning systems can be put in place. There is a need for the characterization of relationships between extreme weather events and health outcomes, especially long-term and mental health effects. There is also a need to know what information is needed and how to communicate that information to the correct groups. Academic communities and policy makers must interact with each other and with groups educating disaster responders and communities to develop sustainable extreme weather event coping strategies and mechanisms to mitigate risk vulnerabilities.

1.02.1 Introduction

The anthropogenic generation of greenhouse gases and ozone-depleting substances has alternating, episodic effects on climate, stratospheric ozone loss, and human health. These effects are influenced by unpredictable natural cycles and extreme events, human resiliency and adaptive behaviors, and global economic and energy policy shifts. Such complex interrelationships affecting human health outcomes cannot be completely explained by predictive epidemiological or geospatial information system-based models and are better described using different paradigms that can account for the entire spectrum of environmental and sociobehavioral events that will occur in coming decades (Pielke et al. in press).

This chapter describes (1) the factors influencing ozone levels in the atmosphere, (2) the beneficial as well as the detrimental effects of ultraviolet (UV) radiation in man, and (3) the global warming potentials and ozone-depleting effects of the most commonly manufactured chlorofluorocarbon (CFC) substitutes in use today. In addition, the impact of UV radiation on marine and terrestrial food chains and ecosystem balance is addressed and supported by actual case studies in ozone layer thinning and excessive UV exposures in high-risk populations of humans and sentinel animals.

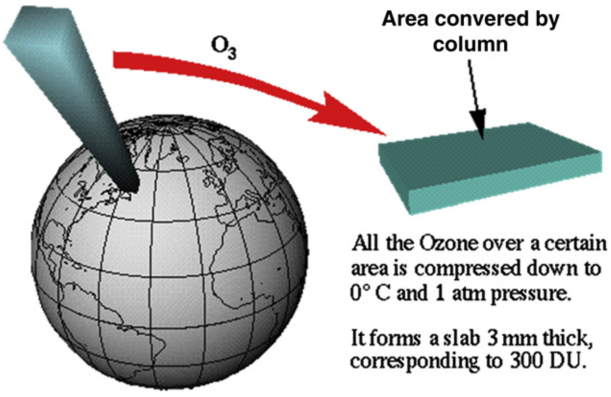
1.02.2 Atmospheric Chemistry and the Ozone Cycle

Ozone is a toxic, water-soluble gas that is irritating to human mucous membranes and can induce upper airway hyperreactivity, precipitate bronchospasm, and aggravate asthma and other chronic lung diseases. Ozone is corrosive and can cause bleaching of painted surfaces, degradation of plastics, and discoloration and death of leafy vegetation (chlorotic mottling). Ozone is a photochemical pollutant and makes major contributions to urban smog, especially during summers and atmospheric inversions. Ozone is composed of three atoms of oxygen and is formed by tropospheric photochemical reactions in which UV radiation from the sun disassembles the oxygen atoms in atmospheric oxygen (O_2), in the oxides of nitrogen (NO_x), and in volatile organic chemicals (VOCs) and reorganizes these singlet oxygen atoms into triatomic ozone (O_3). The atmospheric reactions of the ozone formation cycle are depicted in Figure 1.

Although tropospheric ozone is toxic to man and a major atmospheric pollutant, stratospheric ozone protects life on Earth by absorbing the most harmful wavelengths of UV radiation from the sun. Stratospheric ozone is organized as a thin layer that spreads out between 10 and 50 km in the stratosphere, but is only 3 mm thick if compressed to ground level (Figure 2). The thickness of the stratospheric ozone layer is measured in Dobson units with 1 Dobson unit (DU) being equivalent to 0.01 mm of ozone thickness at standard temperature and pressure (0 °C, 1 atm) (Figure 2). The stratospheric ozone layer effectively absorbs all ultraviolet C (UV-C) and most of the damaging ultraviolet B (UV-B) radiation emitted from the sun in the bandwidths of 290–320 nm, but some UV-B and all higher bandwidth ultraviolet A (UV-A, 320–400 nm) still reach ground level with less photochemical activity, except for some cutaneous and ocular damaging effects.



O_3
Area convered by column
All the Ozone over a certain area is compressed down to 0° C and 1 atm pressure.
It forms a slab 3 mm thick, corresponding to 300 DU.

Figure 2 Measuring the thickness of the stratospheric ozone layer in Dobson units using the Dobson spectrometer. One Dobson unit (DU) is defined as 0.01 mm of ozone thickness at standard temperature and pressure (STP = 0 °C and 1 atm). This figure shows a column of air over Labrador, Canada, which if compressed to STP will form a slab 3 mm thick or 300 DU. 1.02.2.1 The History of Ozone Depletion

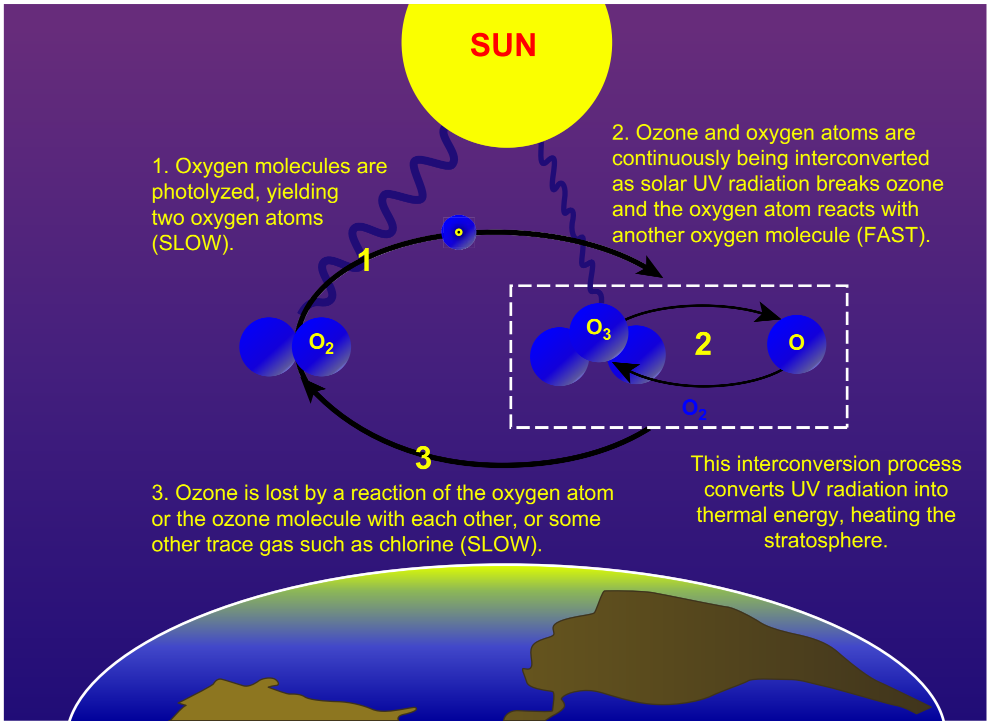
In 1974, Molina and Rowland, who later shared the 1995 Nobel Prize for their research in atmospheric chemistry,



SUN
1. Oxygen molecules are photolyzed, yielding two oxygen atoms (SLOW).
2. Ozone and oxygen atoms are continuously being interconverted as solar UV radiation breaks ozone and the oxygen atom reacts with another oxygen molecule (FAST).
1
o
O_2
O_3

3. Ozone is lost by a reaction of the oxygen atom or the ozone molecule with each other, or some other trace gas such as chlorine (SLOW).
This interconversion process converts UV radiation into thermal energy, heating the stratosphere.

Figure 1 The atmospheric ozone cycle. Source: US Environmental Protection Agency. No copyright permission required. [Available online at http://www.epa.gov/ozone/science/process.html.]

proposed that UV-B protective stratospheric ozone was being destroyed by chemical reactions catalyzed by industrially produced chlorine- and bromine-containing hydrocarbons, particularly the CFCs (Molina and Rowland 1974). The CFCs were commonly used as refrigerants in air conditioning systems, as propellants in spray cans, and even metered dose inhalers (MDIs) for asthmatics (Molina and Rowland 1974). Although inert and environmentally stable in the troposphere, once the CFCs reached the stratosphere they were decomposed by high-energy UV radiation and released reactive chlorine atoms that severed the covalent bonds in ozone (O_3) releasing oxygen (O_2) and chlorine monoxide (ClO) (**Figure 1**) (Farman et al. 1985; NASA Earth Observatory 2011). A single chlorine atom could continue on this ozone-depleting pathway destroying over 100 000 molecules of ozone before becoming a less reactive compound precipitated out of the stratosphere by water vapor, such as hydrochloric acid (HCl) (NASA Earth Observatory 2011). The catalytic activity of chlorine atoms and, to a lesser extent, bromine atoms is responsible for the thinning and perforation of the ozone layer, especially in the polar, low-level ozone layers of the stratosphere (Farman et al. 1985; NASA Earth Observatory 2011). For every 1% decrease in the ozone layer thickness, the amount of UV-B exposure in the lower atmosphere, or troposphere, increases by approximately 2% (NASA Earth Observatory 2011). The average annual decrease in the thickness of the ozone layer in Dobson units is depicted in **Figure 3**.

1.02.2.2 The Ozone Hole

In 1985, Farman and coinvestigators discovered an unanticipated, irregular hole in the ozone layer over the Antarctic and urged the global community to seek CFC alternatives and a ban on CFC production (**Figure 4**) (Farman et al. 1985). Ozone holes developed over the polar regions, primarily over the Antarctic, as temperate region ozone layers thinned and fewer ozone molecules released less heat when absorbing the sun's UV-B rays. This resulted in a cooling of the stratosphere with more polar stratospheric cloud formation and greater generation of reactive chlorine molecules on the surface of ice crystals in the polar clouds.

The size and configuration of the ozone hole has been continuously measured by satellites since 17 September 1979, when the ozone level was 194 DU. From 1979 to 2003, all ozone hole measurements were made by US National Aeronautics and Space Administration's (NASA) Total Ozone Mapping Spectrometer (TOMS) instruments, and from 2003 to the present, the ozone hole has been monitored and measured by the Royal Netherlands Meteorological Institute (KNMI) (NASA Earth Observatory 2011). On 7 October 1989, the year that the Montreal Protocol on Substances that Deplete the Ozone Layer went into effect, the ozone level had dropped to 108 DU. On 9 October 2006, the ozone level measured 82 DU; but by 1 October 2010, the value was back up to 118 DU (NASA Earth Observatory 2011). The lowest value in the ozone layer, reflective of the deepest ozone hole, was measured on 30 September 1994, at 73 DU, while the largest

ozone hole over the Antarctic occurred on 29 September 2000, when the ozone-depleted area stretched for 29.9 million square kilometers or 11.4 million square miles (Figure 4) (NASA Earth Observatory 2011). In 2010, the mean size of the ozone hole was 22.2 million square kilometers (NASA Earth Observatory 2011).

In addition to the human consequences of the Antarctic ozone hole, such as increases in sunburns and photosensitivity disorders, significant ecosystem consequences include melting of the Antarctic ice cap by increased UV radiation with rising sea and tidal levels and ocean surface overheating with reduced phytoplankton productivity in an important marine fishery (Abarca et al. 2002). Recently, a smaller, periodic ozone hole has been observed over the Arctic and was associated with increased UV-B radiation measured in Canada (NASA Earth Observatory 2011). Although ozone holes have been observed over the Antarctic and, to a lesser extent, over the Arctic, these changes in stratospheric ozone levels have occurred over primarily uninhabited areas of the world and not over areas of the world where the vast majority of people live.

1.02.2.3 Case Studies in Ozone Depletion I: Living under the Ozone Hole

In 2001, Abarca and coinvestigators published the results of their 15-year study on the incidence of sunburns and photosensitivity disorders treated by dermatologists in Punta Arenas, Chile, the southernmost large city in the world (population, 145 000), exposed to the Antarctic ozone hole every spring (Abarca et al. 2002). The authors reported a significant increase in the number of patients with severe sunburns during the austral spring of 1999 ($p < .01$), especially noticeable on weekends (29 of 31 cases) with significant ozone depletion days (<250 DU) and increased UV-B radiation (≥300 nm) (Abarca et al. 2002). Although not statistically significant, the incidence of photosensitivity disorders increased 51% over the last 7 years of the investigation (Abarca et al. 2002). The authors concluded that the incidence of serious sunburns increased during the spring of 1999 because of abrupt stratospheric ozone depletion with resulting increase in UV-B radiation at and above 300 nm, the most carcinogenic wavelengths, on days that Punta Arenas was under the Antarctic ozone hole (Abarca et al. 2002).

1.02.2.4 Other Environmental Factors Affecting Stratospheric Ozone Levels

The most significant factors responsible for ozone layer thinning and perforation are the industrial production and atmospheric disposal of halogenated hydrocarbons with the release of ozone-depleting reactive chlorine and bromine atoms. In addition, several other factors may influence stratospheric ozone concentrations including (1) stratospheric sulfate aerosols from volcanic eruptions, (2) stratospheric winds, (3) greenhouse gases, and (4) the increasing use of methyl bromide as an agricultural pesticide. Volcanic plumes can carry sulfur- and chlorine-containing aerosols high into the stratosphere and release more water vapor to form high clouds over the poles, generating more reactive chlorine molecules on ice crystals and further thinning ozone layers and widening the polar ozone holes. Stratospheric winds push the ozone layers around in a repeating cycle, the 26-month quasi-biennial oscillation (QBI), thinning some layers and thickening others. As greenhouse gases heat the troposphere and melt polar ice caps, ocean levels will rise, cooler winds will reduce air temperatures in the lower stratosphere, and more polar clouds will form with ice crystals that trap ozone-depleting chlorine and bromine molecules.

Methyl bromide is a colorless, odorless alkane gas that is used most often as an agricultural fumigant for agricultural commodities, grain elevators, mills, ships, greenhouses, and even furniture warehouses. It is highly effective against a wide range of pests including termites and most other insects, nematodes, rodents, fungi, and weeds. When methyl bromide is applied either as a gas fumigant or as a liquid, only a small amount is transformed into free bromide ions, and most of the volatile gas is released into the atmosphere. Methyl bromide was recognized as a major ozone-depleting substance by the Montreal Protocol and the US Clean Air Act, and its use was incrementally reduced in the United States and in other Montreal Protocol signee nations, until its complete phase-out from use on 1 January 2005. Nevertheless, methyl bromide has a long atmospheric half-life and remains in use as a gas fumigant under several allowable exemptions. In addition, methyl bromide gas is still used by non-UN member nations not participating in the Montreal Protocol and its subsequent amendments.

1.02.3 The Chronology of Stratospheric Ozone Depletion

Table 1 summarizes the chronology of stratospheric ozone depletion and the world's mitigation efforts to date beginning with the Montreal Protocol in 1987. The average annual depletion in stratospheric ozone levels in Dobson units for the 30° N to 40° N latitude band in response to the Montreal Protocol and its Amendments is depicted by the graph in Figure 3.

1.02.3.1 The Ozone-Depleting Chemicals

Although the CFCs were the first ozone-depleting substances to be manufactured and recognized as contributing to stratospheric ozone depletion, there are many other ozone-depleting chemicals that continue to be produced worldwide, including CFC substitutes. The major uses of the CFCs and CFC substitutes are depicted in Figure 5. The ozonedepleting chemicals are now identified by an international nomenclature that immediately identifies the substance as ozone depleting and concisely describes its chemical structure. The chlorine (or bromine) atoms in the chemical's structure make the chemical an ozone-depleting substance. All ozone-depleting chemicals and their substitutes are inert and environmentally stable in the atmosphere where they can remain for decades. Some of the ozone-depleting substances and their substitutes are summarized in Table 2. The lifetimes, total chlorine contributions, and global warming contributions relative to carbon dioxide of some selected ozone-depleting substances are summarized in Table 3.

1.02.3.2 Public Perception of Stratospheric Ozone Depletion

Public misperceptions about climate and stratospheric ozone depletion have a long history and continue to abound today. In 2010, Reynolds and coinvestigators reported the results of a study that compared the results of a 1992 survey on global warming and ozone depletion distributed to educated laypeople with the same survey administered to similar study subjects in 2009 (Reynolds et al. 2010). The investigators reported the following results (Reynolds et al. 2010): (1) In 1992, most respondents were unaware of the role of anthropogenic carbon dioxide emissions in global warming and often confused global climate change and stratospheric ozone depletion (Reynolds et al. 2010); (2) In 2009, most survey respondents showed higher awareness and comprehension of some climate change causes, identified energy use as a major cause of climate change, and rarely mentioned ozone depletion in the context of global warming (Reynolds et al. 2010). The authors concluded that many educated individuals still had incorrect beliefs about climate mechanisms and stratospheric ozone depletion (Reynolds et al. 2010).

Until 2000, ozone-depleting CFCs served as propellants for MDIs used by asthmatics and others with bronchospastic lung

Table 1 The chronology of stratospheric ozone depletion by chlorofluorocarbons (CFCs) and worldwide mitigation efforts

Year	*Ozone depletion recognition and mitigation efforts*
1913	Fabry and Buisson discover the ozone layer in the earth's atmosphere.
1928	Thomas Midgley, Jr., produces dichlorofluoromethane, the first CFC, later patented by DuPont as Freon®.
1930	General Motors and DuPont formed the Kinetic Chemical Company to mass produce Freon®.
1932	The Carrier Engineering Corporation used Freon® to produce the first self-contained home air conditioning unit, calling it an "Atmospheric Cabinet."
1935	Frigidaire and its competitors had sold eight million new refrigerators using Freon® in the United States.
1945–60s	One million metric tons of CFCs were sold annually for $1 billion (United States); air conditioning became affordable for homes, automobiles, and offices with Freon® as the preferred coolant in most systems; municipal public health codes were revised to designate Freon® as the only coolant that could be used in public buildings. CFCs were used in aerosol spray cans, paints, hair conditioners, and health care products.
1974	Molina and Rowland published the first study that confirmed that increase of chlorine levels from the breakdown of atmospheric CFCs significantly reduced the levels of stratospheric ozone.[a]
1975	Ramanathan published the first study that demonstrated greenhouse gas effect enhancement by CFCs augmenting increasing global surface temperatures from fossil fuel consumption.[b]
1978	US Environmental Protection Agency (EPA) bans CFCs in aerosol sprays in the Toxic Substance Control Act and Federal Food, Drug, and Cosmetic Act.
1985	Farman, Gardiner, and Shanklin published the first paper on the Antarctic ozone hole.[c]
1985	Vienna convention established a framework for 20 nations to share research and scientific assessment of ozone depletion, and to develop a protocol that would provide specific targets for CFC releases. No consensus was reached.
1987	Montreal Protocol signed by 43 nations. Participants agreed to freeze CFC production at 1986 levels and reduce production by 50% by 1999.
1990	Title VI of the US Clean Air Act directed the EPA to protect the ozone layer through regulatory and voluntary programs.
1995	Molina and Rowland received the Nobel Prize in Chemistry for their research in atmospheric chemistry.
1997	Kyoto Protocol to limit greenhouse gas emissions was adopted by many nations except the United States, China, and others.
2000	Largest single-day ozone hole over Antarctica covered 11.4 million square miles.
2006	Ozone hole reached prior record size, set a new record for lowest ozone concentrations and the deepest ozone hole observed.
2009	All 196 countries in the United Nations and the European Union ratified the original Montreal Protocol.
2011	Scientists detected a record of 40% depletion of Arctic ozone from winter to late March, breaking the prior record of 30%.

Table 2 Some ozone-depleting substances and their substitutes

Prefix	*Meaning*	*Atoms in one molecule*	*Ozone-depleting substance or substitute*
CFCs	Chlorofluorocarbons	Cl, F, C	Depleting substance
HCFCs	Hydrochlorofluorocarbons	H, Cl, F, C	Depleting substance
HBFCs	Hydrobromofluorocarbons	H, Br, F, C	Depleting substance
Halon-Br, Cl	N/A	Br, Cl	Depleting substance
HFCs	Hydrofluorocarbons	H, F, C	Substitute
HCs	Hydrocarbons	H, C	Substitute
HFEs	Hydrofluoroethers	H, F	Substitute
PFCs	Perfluorocarbons	F, C	Substitute
Halon F, H	N/A	F, H	Substitute
Halon C	N/A	C	Substitute
HFAs	Hydrofluoroalkanes	H, F, C	Substitute

N/A, not applicable.

Table 3 The lifetimes, total chlorine, and potential global warming contributions of selected chlorinated and brominated fluorocarbons relative to carbon dioxide

Common names	*Chemical formulas*	*Lifetime (in years)*	*Total chlorine contributions (%)*	*Global warming contributions over 20 years (GWP units)*[a]
Carbon dioxide	CO_2	NA	0	1
CFC-11	CCl_3F	45	21	6730
CFC-12	CCl_2F_2	100	18	11 000
CFC-22	$CHClF_2$	12	1.6	5160
CFC-113	CCl_2FCClF_2	85	5	6540
Halon-1211	$CBrClF_2$	16	8	4750
Halon-1301	$CBrF_3$	65	3	8480
HFC-134a	CH_2FCF_3	14	0	3830

[a] *GWP units, global warming potential units. GWP is defined as the given mass of a chemical that contributes to global warming over a given period relative to carbon dioxide, which has a GWP of 1.0.*

conditions to relieve bronchospasm and improve breathing (Boulet 1998). The Montreal Protocol recognized the ozone-depleting properties of CFCs in MDIs and mandated a gradual phase-out of their use over the next decade as new non-CFC-containing MDIs were developed (Boulet 1998). In 1998, Liam and Lim reported the results of a survey study to assess the awareness of the ozone layer and its depletion by CFCs in MDIs among 113 consecutive asthmatic patients aged 12 years and older (Liam and Lim 1998). The investigators reported the following results (Liam and Lim 1998). (1) Although 65% of the patients were aware of the existence of the ozone layer, only 23% knew that CFCs played a major role in ozone depletion (Liam and Lim 1998). (2) Only 10% of the survey respondents knew that their MDIs used ozone-depleting CFCs as propellants (Liam and Lim 1998). (3) When informed of the role of CFC propellants in ozone depletion, 81% of 94 patients who preferred CFC-containing MDIs were willing to switch to multidose, dry powder inhalers once available on the market (Liam and Lim 1998). In summary, well-designed survey studies have now demonstrated that a majority of the lay public still do not understand the UV protective role of the ozone layer and the role of CFCs in ozone depletion.

1.02.3.3 The Time Line to Stratospheric Ozone Layer Restoration

Although atmospheric chlorine levels are decreasing, several factors will prolong the time line to restoration of pre-1980 thickness levels of the ozone layer, including rising bromine levels in many CFC substitutes, which continue to degrade ozone, and increasing volcanic eruptions with more halogen-trapping ice crystals in stratospheric clouds (Table 2) (McKenzie et al. 2003). Other factors that will prolong the time line to ozone layer restoration include the long half-life of phased-out CFCs and some of the ozone-depleting CFC substitutes and rising tropospheric ozone levels from photochemical effects on fossil fuel emissions (DeFabo 2005; Wilson et al. 2007; Tang et al. 2011). As tropospheric ozone levels increase and stratospheric ozone levels stabilize, there will be a change in the atmospheric chemistry of the boundary layer between the troposphere and the stratosphere with an increase in oxidation potential of the boundary layer, especially at the poles, which may allow other halogens, such as iodine, to enter the stratosphere and deplete ozone (DeFabo 2005; Wilson et al. 2007; Tang et al. 2011). Recent atmospheric modeling studies have suggested that elemental iodine, radioactive iodine from accidental nuclear power plant releases, such as occurred at the Fukushima Daiichi Nuclear Power Plant following an earthquake-generated tsunami in March 2011, and other iodine-containing substances from natural sources, such as the oceans, may increase stratospheric ozone depletion significantly in the polar regions during spring (Wilson et al. 2007).

1.02.4 Direct versus Indirect Human Health Effects of Ozone Depletion

The adverse health effects of stratospheric ozone depletion may be divided into direct and indirect health effects of increased UV-B radiation. The direct health effects of UV-B radiation include damage to target receptors in the skin, eyes, and cellular immune system. UV-B radiation damages DNA at neighboring pyrimidine sites and can cause mutations in p53 tumor suppressor genes precisely at these sites, resulting in squamous cell carcinomas (SCCs) (Brash et al. 1991; Ziegler et al. 1993). The risks of cutaneous SCCs increase with lifelong sun exposures, but basal cell carcinomas (BCCs) and melanomas appear to be more related to intermittent UV overexposures with severe sunburns in childhood than to prolonged exposures (Holman and Armstrong 1984). Skin cancers are the most common types of cancers, and the incidence of all three types of skin cancers is increasing with increasing UV-B radiation exposures (Brash et al. 1991).

Although the carcinogenic effects of UV-B radiation on the skin have been well studied, UV-B effects on the eyes are less certain, but animal and epidemiological investigations support association of cortical cataracts with excessive UV radiation (Dolin 1994). The incidence of cortical cataracts has now been predicted to rise by 0.5% for every 1% persistent decrease in stratospheric ozone, but such predictions will ultimately be confounded by UV-A and UV-B resistant glasses, aging of the world's population, and steroid-containing medication-induced cataract formation (Van der Leun et al. 1993).

The least well-studied adverse health effects of increased UV-B radiation are its effects on cellular immunity, which could result in increases in both malignant and infectious diseases (Van der Leun et al. 1993). As cellular immunity wanes with age and UV-B exposure, hematopoietic malignancies, such as non-Hodgkin's lymphoma, may increase, but such increases would be confounded most significantly by population aging and by technological advances in diagnostics and treatments (Van der Leun et al. 1993). Improvements in diagnostics will lead to more specific diagnoses (diagnostic biases), and as more effective treatments prolong the life of patients with hematopoietic malignancies, these diseases will become more prevalent (length-time biases). Increased UV-B exposures will likely cause greater severity of infectious diseases that have significant phases in the skin, such as herpes and infection by human papilloma viruses (HPVs) (Miura et al. 1994). Herpes labialis or "cold sores" on the lips triggered by sun exposures are frequent examples of local UV-B-induced immunosuppression with recrudescent infections (Miura et al. 1994).

The indirect health effects of UV-B radiation are caused by the impact of increased UV-B irradiation on the environment and include greater tropospheric contributions to photochemical smog, with aggravation of chronic respiratory diseases, such as asthma and chronic obstructive pulmonary disease (COPD) (Van der Leun et al. 1993). More dramatic indirect effects of ozone depletion and increased UV-B radiation could stem from diminished world food production as a result of UV-B effects on agricultural crops and marine fisheries.

1.02.4.1 Are There any Beneficial Human Health Effects from Ultraviolet Radiation?

The most significant beneficial health effect of limited daily exposure to UV-B radiation is the photochemically driven production of vitamin D_3 from 7-dehydrocholesterol in the skin, which is then converted to its active metabolite, 1, 25-dihydroxy vitamin D (Rhodes et al. 2010; Holick et al. 1982). Vitamin D is essential for bone health, especially in estrogen-deficient and postmenopausal women, but any deficiencies in vitamin D from reduced UV-B exposures could be easily tempered by vitamin supplements and vitamin D-fortified foods, such as bread and milk. In addition, the production of biologically active vitamin D in the skin is self-limiting and controlled by a feedback loop mechanism that maintains constant levels (Holick et al. 1982). In a 2010 study designed to measure the amount of time spent in summer sunlight to maintain sufficient vitamin D levels ($\geq 20\ \text{ng ml}^{-1}$) in humans, Rhodes and colleagues exposed 120 British Caucasians wearing T-shirts and shorts to simulated summer's sunlight exposures in Manchester, United Kingdom (53.5° N), and determined that 13 min of summer sunlight exposures to 35% of skin surface areas would produce sufficient ($\geq$20 ng ml^{-1}) but not optimal levels ($\geq$32 ng ml^{-1}) of vitamin D_3 at UK latitudes (Rhodes et al. 2010).

Although there is conclusive evidence to support the critical role of vitamin D in bone metabolism, there is much less conclusive evidence to support its role as being protective against internal cancers, such as colorectal cancer, and chronic neurological diseases, such as multiple sclerosis (Holick et al. 1982). Multiple sclerosis is indeed more prevalent at higher latitudes with less UV radiation and more vitamin D insufficiency (Norval et al. 2011). However, such an association is confounded by postinfectious autoimmune activity stimulated by more frequent viral infections in higher latitudes with colder climates, family history of chronic demyelinating diseases, and vitamin D supplementation.

1.02.4.2 Measuring Human Exposures to Ultraviolet Radiation: The UV Index

The UV index was initially introduced in Canada in 1992 in response to growing concerns about increasing human exposures to excessive UV radiation due to stratospheric ozone depletion (Fiolitov et al. 2010). In 1994, the UV index was adopted as the standard indicator of UV levels by both the World Meteorological Association and the World Health Organization (WHO) (Fiolitov et al. 2010). The UV index is a daily calculated measure of the strength of solar UV radiation projected on a national map and reflected on a multicolor, visual analog scale from a low exposure level of 1 to an extremely high exposure level of 11+ (Figure 6) (Norval et al. 2011). UV index values can be calculated from satellite measurements of cloud cover and stratospheric ozone using radiation transfer models or measured by ground-based spectrometers, broadband filter radiometers, or multifilter radiometers (Fiolitov et al. 2010). Over the United States and Canada, mean noontime UV index values in summer will range from 1.5 in the Arctic to over 11+ in Texas and Hawaii (Figure 6) (Fiolitov et al. 2010). Several other temporal and physical factors can affect the UV index in addition to ozone levels and cloud cover and include time of the day, season of the year, sun angle of elevation, altitude, latitude, air pollution, rain, and snowfall (Fiolitov et al. 2010). In the United States, the National Weather Service calculates the predicted UV index for the next day in every region and posts its results on the US Environmental Protection Agency (EPA) website (http://www.epa.gov/sunwise/uvindex.html), where individuals may register to receive personal e-mail notifications of high-UV alerts in order to take precautions from excessive UV exposures outdoors (Table 4).

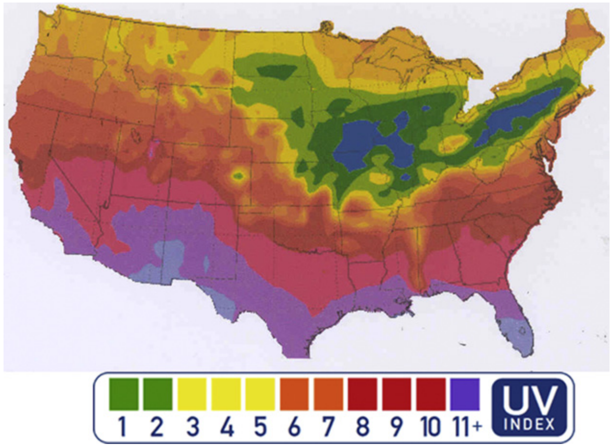

Figure 6 The daily (29 August 2011) UV index forecast map of the United States and color legend. Source: US Environmental Protection Agency. No copyright permission required. [Available online at http://www.epa.gov/sunwise/uvindex.html.]

1.02.4.3 Cutaneous Effects of Excessive Ultraviolet Radiation

The uncovered skin is exposed to UV radiation outdoors, receives the largest doses of UV radiation, and suffers the most significant adverse effects, including photoaging, sun allergy, premalignant skin lesions (actinic keratoses (AK)), and skin cancers of which the most common types are classified as nonmelanoma skin cancers (NMSCs; BCC and SCC) and cutaneous malignant melanoma (CMM) (Narayanan et al. 2010). Skin cancers exhibit different sun exposure-related risk factors with early, intermittent overexposures and blistering sunburns associated with BCC and CMM, and chronic and cumulative overexposures associated with SCC (Rittié et al. 2007; Diepgen and Mahler 2002; World Health Organization 2011; Preston and Stern 1992).

1.02.4.3.1 Nonmelanoma Skin Cancers

The nonmelanoma skin cancers (NMSCs) include BCC and SCC, comprise 95% of all skin cancers, and are the most commonly occurring malignancies among fair-skinned populations worldwide (Narayanan et al. 2010; Diepgen and Mahler 2002; World Health Organization 2011). The world incidence of NMSCs is estimated to be 2–3 million cases each year (Narayanan et al. 2010; Rittié et al. 2007; Diepgen and Mahler 2002; World Health Organization 2011; Preston and Stern 1992). An upward trend in NMSCs has now been observed in Australia, Europe, and the United States, with an average annual increase between 3 and 8% (Diepgen and Mahler 2002; World Health Organization 2011; Preston and Stern 1992).

Dark-skin populations are protected from UV radiation by increased levels of epicutaneous melanin and have significantly lower annual incidence rates of NMSCs (Gloster and Neal 2006). Epicutaneous melanin in Blacks filters twice as much UV-B radiation as does that in Whites (Gloster and Neal 2006). The epidermis in Blacks transmits 7.4% of UV-B and 17.5% of UV-A rays, compared with 24 and 55% in Whites, respectively (Gloster and Neal 2006).

BCC now accounts for 80–85% of all NMSCs and is the most common malignancy in Whites (Diepgen and Mahler 2002; World Health Organization 2011; Preston and Stern 1992). BCC is the most commonly diagnosed cancer in the United States and now accounts for approximately 30% of all cancer diagnoses (World Health Organization 2011). The annual worldwide incidence rate of BCC is increasing by nearly 10%, with the highest rates in elderly men (Diepgen and Mahler 2002; World Health Organization 2011). Although BCCs may occur anywhere on the body; they usually occur as

Table 4 Interpreting the US Environmental Protection Agency's daily UV index map

UV index number	*Index map color code*	*UV exposure category*	*Recommended exposure protection*
1-2	Green	Low	Sunglasses, sunscreens 15+
3-5	Yellow	Moderate	Hat, sunglasses, sunscreens 15+
6-7	Orange	High	Hat, sunglasses, sunscreens 15+, long-sleeved shirt and long pants, avoid midday exposures
8-10	Red	Very high	Hat, sunglasses, consider sunscreens 30+, long-sleeved shirt and long pants, avoid exposures from 10 a.m to 4 p.m., bright surfaces (sand, snow, water) reflect and double uv exposures
11+	Purple	Extreme	Hat, sunglasses, sunscreens 30+, long-sleeved shirt and long pants, avoid exposures from 10 a.m to 4 p.m., bright surfaces (sand, snow, water) reflect and double uv exposures

nonhealing ulcers or papulonodules on sun-exposed areas, especially on the head (nose, ears) and neck, and rarely metastasize (Figure 7) (Rittié et al. 2007; Diepgen and Mahler 2002; World Health Organization 2011; Preston and Stern 1992). The most significant risk factors for BCCs are repeated overexposures to UV-B irradiation, even without sunburns, in childhood and as young adults. Although BCCs develop slowly and rarely metastasize to other organs, they can be locally and deeply invasive, very disfiguring, and place significant financial and utilization burdens on health care systems worldwide (Rittié et al. 2007; Diepgen and Mahler 2002; World Health Organization 2011; Preston and Stern 1992).

SCCs begin in the uppermost layer of the skin, account for approximately 15% of all skin cancers, and have a 10-fold greater risk for metastasis and death than BCCs (Narayanan et al. 2010; Rittié et al. 2007; Diepgen and Mahler 2002; World Health Organization 2011; Preston and Stern 1992). Both BCCs and SCCs arise from keratinocytes in the epidermis, the former probably from a pleuripotential stem cell. SCCs usually occur in sun-exposed areas of the head (ears), face (nose, lips, and eyelids), neck, and hands and may be heralded by premalignant AK, rough and scaly pink patches (Figure 8) (Narayanan et al. 2010; Rittié et al. 2007; Diepgen and Mahler 2002; World

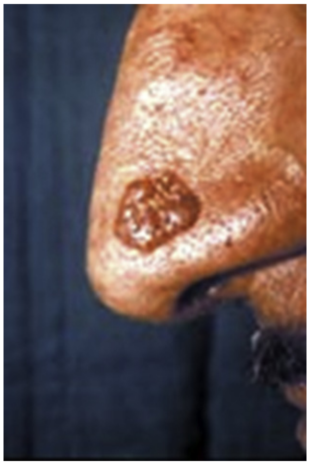

Figure 7 Ultraviolet radiation-induced basal cell carcinoma on the left side of the nose. Basal cell skin cancers erode tissue locally, can be quite disfiguring, and do not usually spread or metastasize distantly to other organs. Source: US Centers for Disease Control and Prevention (CDC). No copyright permission required. [Available online at http://www.cdc.gov/excite/skincancer/mod10.thm.]

Health Organization 2011; Preston and Stern 1992). Smokers, roofers, and asphalt road workers are exposed to combinations of aerosolized carcinogenic polycyclic aromatic hydrocarbons and UV radiation and are predisposed to SCCs in sun-exposed areas, such as the face, arms, and hands (Table 5) (Narayanan et al. 2010; Rittié et al. 2007; Diepgen and Mahler 2002; World Health Organization 2011; Preston and Stern 1992). In women, both BCCs and SCCs occur more commonly on the legs than in men as a result of greater sun exposures at these sites (Diepgen and Mahler 2002).

The most commonly used measure to gauge the potential increase in NMSC incidence rates related to ozone depletion and increased UV-B exposure is the amplification factor (AF) (Rubenstein et al. 1999). The AF is the percentage increase in NMSCs that would result from a 1% decrease in stratospheric ozone (Rubenstein et al. 1999). The AFs for BCC and SCC are 1.7 and 3.0, respectively (Rubenstein et al. 1999). Therefore, for each 1% sustained decrease in stratospheric ozone, the annual incidence rates for BCCs and SCCs in fair-skinned persons will

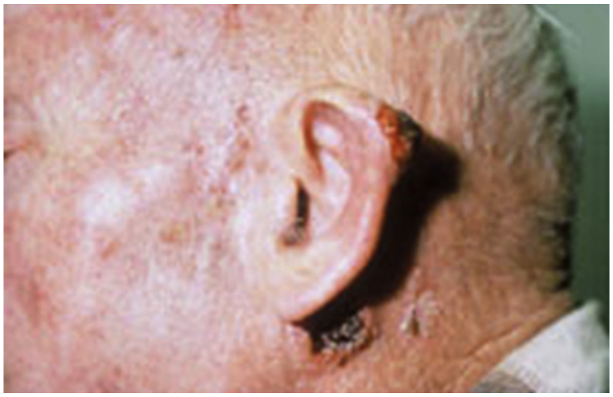

Figure 8 Ultraviolet radiation-induced squamous cell carcinoma on the left ear and mastoid process. Squamous cell skin cancers erode tissue locally, can be quite disfiguring, and can spread or metastasize distantly to other organs. Table 5 Risk factors and prevention strategies for skin cancer

Risk factors for skin cancer	*Prevention strategies for skin cancer*
UV radiation exposure	**Minimize sun exposure**
UV-A	Especially during peak sun hours, 10 a.m. to 4 p.m.
UV-B	
Immunosuppression	**Sun protection**
UV radiation	UV-A and UV-B resistant wrap-around sunglasses
Acquired immunodeficiency syndrome (AIDS)	Sun protective clothing with tightly woven fabric
Immunosuppressive therapy	Wide-brim hat
Organ transplant antirejection therapy	
Genetic syndromes	**Sunscreens**
Basal cell nevus syndrome	Sunscreen with high SPF, ≥15
Epidermodysplasia verruciformis	Apply sunscreen to children ≥6 months of age
Oculocutaneous albinism	Reapply sunscreen every 2 h while outdoors, even on non-sunny days
Xeroderma pigmentosum	
Clinical therapies	**Avoid artificial tanning (beds and booths)**
Phototherapy	
Psoralen + UV-A therapy (PUV-A)	
Viruses and infections	**Sun safety education**
Human immunodeficiency virus	Age-appropriate public health education
Human papilloma virus	Directed skin cancer education: families, coaches, teachers, administrators, primary care physicians
Environmental pollutants and chemical carcinogens	**Screening**
Arsenic	Periodic free screening programs
Chromium	
Polycyclic aromatic hydrocarbons	
Ionizing radiation	**Skin examinations**
X-rays	Mole watch
	Frequent self-screen examinations
	Skin examinations by dermatologists
Miscellaneous risk factors	**Policies, services, and organizations**
Advancing age	Promotion of health services and organizations that support skin cancer education
Alcohol intake	Planning and implementation of national public health policies that reduce UV exposures in populations
Artificial tanning	
Dermatoses and keratoses	
Fair skin color	
Nonhealing wounds and scars	
Outdoor occupations	

increase by 1.7 and 3.0%, respectively (Rubenstein et al. 1999). The combination of the increased carcinogenic potential of UV-B at 300 nm and the UV-B absorption spectrum for stratospheric ozone would result in a calculated AF of 1.6% or a 10% decrease in ozone (Rubenstein et al. 1999). If sustained, this level of ozone depletion would increase the annual incidence of BCCs by 30% and SCCs by 50% among fair-skinned persons worldwide (Rubenstein et al. 1999).

1.02.4.3.2 Cutaneous Malignant Melanoma

Cutaneous malignant melanoma (CMM) accounts for approximately 5% of skin cancers worldwide and has the highest case fatality rates (World Health Organization 2011). CMM is now the most commonly increasing malignant disease, with an estimated annual incidence rate increase of 3–7% (World Health Organization 2011). The WHO has estimated that 132 000 new cases of melanoma will occur each year worldwide (World Health Organization 2011). In the United States, melanomas comprise 3–5% of skin cancers, but account for approximately 75% of skin cancer deaths (Holman and Armstrong 1984). In 2010, an estimated 68 130 people in the United States were diagnosed with melanoma, and an estimated 8700 patients died, according to the US National Cancer Institute. Annual melanoma incidence rates in the United States are 16 times greater in Whites than African–Americans and 10 times greater in Whites than in Hispanics (Holman and Armstrong 1984; Narayanan et al. 2010). About 1 in 50 people in the United States will be diagnosed with melanoma at some point in their lives (Holman and Armstrong 1984; Narayanan et al. 2010).

Melanomas begin in melanocytes, are usually darkly pigmented, and occur more commonly on the trunk in men and on the legs in women (Figure 9) (Diepgen and Mahler 2002). Melanomas are more common in fair-skinned people with light-colored eyes (blue, green) and blond or red hair (Diepgen and Mahler 2002). The characteristic physical features of melanomas, often described as the ABCDs of melanomas, include (1) asymmetric shape, (2) border irregularity, (3) combination of colors, and (4) diameters larger than a pencil eraser (6 mm) (Figure 9). Besides ethnicity and family history, the greatest risk factors for melanomas include three or more blistering sunburns before age 18–20 years, congenital nevi (moles), large numbers of moles, and long-term phototherapy with psoralens and UV-A (PUV-A) (Table 5). Although an association between UV-B overexposures and NMSCs has been well established, the relationship between UV-A exposure and melanoma is not as clear, but supported by several observations including the greater carcinogenicity of low-bandwidth UV-A in PUV-A therapy as a risk factor for both NMSCs and melanomas (Diepgen and Mahler 2002; Salmon et al. 2007).

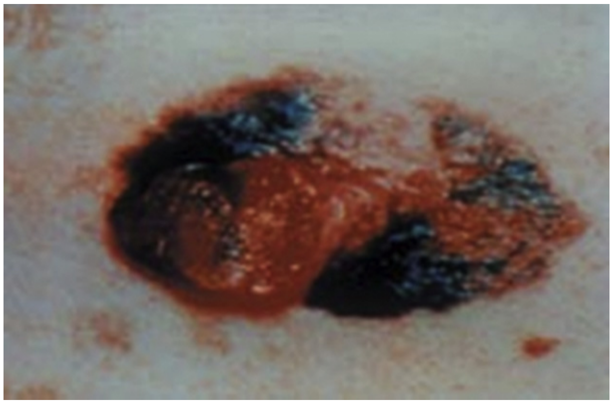

Figure 9 Ultraviolet radiation-associated malignant melanoma. Note the asymmetric and irregular border and the multiple color shades. Malignant melanomas must be managed with early and aggressive surgical excision and will frequently spread or metastasize distantly to other organs. Source: US Centers for Disease Control and Prevention (CDC). No copyright permission required. [Available online at http://www.cdc.gov/excite/skincancer/mod10.thm.]

1.02.4.4 Case Studies in Ozone Depletion II: Cutaneous Malignant Melanomas in New Zealand

In the United States, CMM is the sixth most common cancer in males and the seventh most common cancer in females per capita, but in Australia and New Zealand, melanoma is the fourth most common cancer in males and the third most common cancer in females per capita (Salmon et al. 2007). Although the incidence rates for melanoma were comparable in Queensland, Australia, and New Zealand throughout the 1980s, melanoma incidence rates in New Zealand have now surpassed incidence rates in neighboring Australia and have become the highest incidence rates for melanoma in the world, especially in the Tauranga region of New Zealand (Salmon et al. 2007).

In order to determine the incidence of melanoma in the Tauranga region (Tauranga and Western Bay of Plenty Regions, North Island of New Zealand), Salmon and coinvestigators reviewed all histopathological reports of both in situ and invasive melanomas in the region reported during 2003 and compared the age-standardized incidence rates for the Tauranga region stratified by the entire population and non-Maori population with incidence rates in Australia and the Northern Hemisphere (Salmon et al. 2007). The age-standardized incidence of invasive melanoma in the non-Maori population was 79/100 000, and the age-standardized rate for the entire population was 70/100 000 (Salmon et al. 2007). The rate of in situ melanoma was 78/100 000 for the non-Maori population and 72/100 000 for the entire population (Salmon et al. 2007). The investigators attributed the exceptionally high incidence of melanomas in Tauranga, New Zealand, to the higher levels of UV irradiation in areas of the Southern Hemisphere under the ozone hole and to the relatively cool summer temperatures of the region, which encouraged outdoor exposures, especially among the fair-skinned population of the region (Salmon et al. 2007).

1.02.4.5 Ocular Effects of Excessive Ultraviolet Radiation

Although UV radiation is a recognized risk factor for conjunctival pterygia and cortical cataracts, the scientific evidence to support an association between UV exposure and retinal malignant melanoma and age-related macular degeneration of the retina is not as powerful. The ocular effects of acute and chronic UV-B on the eyes and eyelids are summarized in Table 6 (Jones 1992; Norval et al. 2007; Schein et al. 1995). Besides excessive solar UV exposure, other well-known risk factors for conjunctival pterygia include male gender, outdoor occupation or avocation, and proximity to the equator (Figure 10).

Table 6 The acute and chronic effects of UV-B exposure on the eyes and eyelids

Ocular structures	*Acute UV-B effects*	*Chronic UV-B effects*
Eyelids	Sunburn Blistering Exfoliation Hyperpigmentation	Freckling Lentigines (age spots) Hypomelanosis (vitiligo) Actinic keratosis Nonmelanoma skin cancers (BCC, SCC) Malignant melanoma Drug-induced photosensitivity
Conjunctiva	Chemosis (swelling) Photoconjunctivitis Reactivation of herpes simplex keratoconjunctivitis	Dyskeratosis Intraepithelial neoplasia Pinguecula
Cornea	Photokeratitis Endothelial damage Reactivation of herpes zoster ophthalmicus	Climatic droplet keratopathy Endothelial changes Pterygium
Lens	Anterior subscapular opacities	Cortical cataract
Retina	Not applicable presently	Potentially retinal malignant melanoma and aggravation of age-related macular degeneration

BCC, basal cell carcinoma; SCC, squamous cell carcinoma.

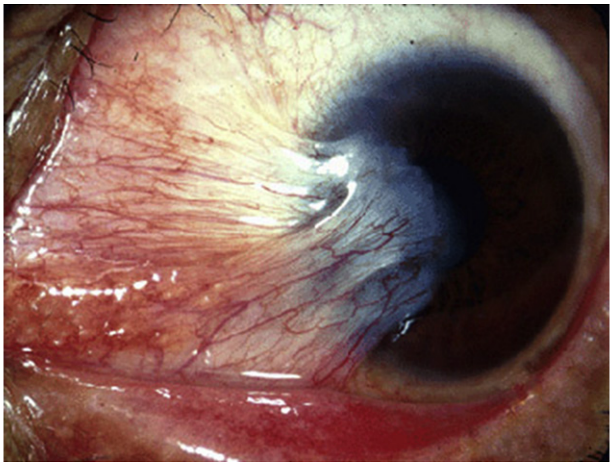

Figure 10 Conjunctival pterygium. The well-known risk factors for conjunctival pterygia include male gender, outdoor occupation or avocation, proximity to the equator, and excessive solar UV exposure. 1.02.4.6 Immune System Effects of Excessive Ultraviolet Radiation

UV-induced immunosuppression can act both locally and systemically to adversely affect the skin's immune systems as the first barriers against viral skin infections and carcinogenesis by the following mechanisms: (1) diminishing antigen-presenting cell functions, (2) inducing production of immunosuppressive cytokines, (3) modulating contact and delayed-type hypersensitivity reactions, and (4) suppressing cell-mediated immunity (Narayanan et al. 2010). UV-induced immunosuppression contributes to the progression of both melanoma and NMSC by causing DNA damage, interfering with DNA repair, and inhibiting p53 tumor suppression genes (Narayanan et al. 2010; Rittié et al. 2007). Nevertheless, the exact mechanisms of UV-induced immunosuppression and its relationships to the induction of skin cancers have not been fully elucidated.

Epidemiological investigations have now supported associations between UV exposures and NMSCs in immunosuppressed transplant recipients, between UV exposures and reactivations of cutaneous herpes simplex viral (HSV) infections, and between UV exposures and HPV-associated infections and NMSCs (Ichihashi et al. 2004; Akgul et al. 2006). Renal transplant recipients taking immunosuppressive therapies are more susceptible to skin cancers, 90% being NMSCs, if they are light skinned and have frequent UV-B exposures (Terhorst et al. 2009).

1.02.4.7 Special Populations at Increased Risks of Ultraviolet Radiation-Induced Skin Cancers

Besides fair-skinned persons, other special populations at increased risks of UV-induced skin cancers include children and organ transplant recipients (OTRs) (Centers for Disease Control and Prevention 2011). In children, skin cancer risks associated with UV exposures are greater for CMM than for NMSCs (Centers for Disease Control and Prevention 2011). Since 80% of major sun overexposures occur before the age of 18 years, children are at the greatest risk of developing CMM as young adults (Centers for Disease Control and Prevention 2011). Children who have suffered blistering sunburns are five times more likely to develop CMM as young adults than children who have never had sunburns (Centers for Disease Control and Prevention 2011).

Epidemiological investigations have now supported associations between UV exposures and NMSCs in immunosuppressed OTRs (Terhorst et al. 2009). In 2009, Terhorst and coinvestigators assessed the risk factors for NMSCs in OTRs in a questionnaire study that enrolled 70 OTRs who had developed skin cancer after transplantation compared to 69 matched OTRs who had no history of skin cancer (Terhorst et al. 2009). The investigators found the skin cancer group to have fairer skin color than controls ($p < .05$), to have received greater recreational sun exposures ($p < .05$), and to have been transplanted at younger ages ($p < .001$) for longer time periods ($p < .001$) than controls (Terhorst et al. 2009). In addition, the skin cancer group was more likely to have a past or present history of immunosuppression with azathioprine ($p < .05$) (Terhorst et al. 2009).

In addition to UV-exposed transplant recipients and patients with oncogenic viral infections, patients with two rare, genetic skin diseases, epidermodysplasia verruciformis and xeroderma pigmentosum (XP), will also demonstrate enhanced UV-induced inflammation and a higher incidence of NMSCs in sun-exposed body sites (Kraemer et al. 1978). Patients with XP have mutations that inhibit DNA repair following UV-induced DNA damage and demonstrate a significant propensity to develop NMSCs following UV exposures, up to 5000 times that of the general population (Kraemer et al. 1978).

UV exposures are well-known stimuli for reactivations of type 1 HSV infections presumably from suppression of local immune responses that permit immunologically unimpeded viral travel down sensory nerves and subsequent replication at sites of initial viral infections (Ichihashi et al. 2004). In a Japanese study of 2656 patients with recurrent HSV infections, the self-reported cause of recurrent cold sores was solar UV exposure in 10.4%, rising to 19.7% overall and 40% in subjects younger than 30 years during the summer months (Ichihashi et al. 2004). UV exposure and prior infections with cutaneous HPV can act as cofactors in the development of NMSCs presumably from a combination of complex mechanisms including UV-induced epicutaneous apoptosis, local immunosuppression, and HPV-induced malignant cell proliferation (Akgul et al. 2006).

Unlike the significant associations between UV exposures and NMSCs in transplant recipients and in patients with genetic or viral diseases, there is no evidence to support UV irradiation serving as a risk factor for hematopoietic malignancies, such as non-Hodgkin's lymphoma (Hartage et al. 1996). Although immunosuppression from cancer or antirejection chemotherapies are indeed risk factors for both NMSCs and non-Hodgkin's lymphoma, this does not support UV exposure as a common causative factor for these cancers (Hartage et al. 1996). In addition, the incidence rate of non-Hodgkin's lymphoma does not share a similar southward latitudinal gradient with the incidence rates of NMSCs in the United States (Hartage et al. 1996).

UV radiation-induced immunosuppression may be a significant risk factor for skin cancer in both immunosuppressed and immunocompetent patients and for the reactivation of viral infections with cutaneous or mucosal phases. In addition, there is some evidence for the synergistic effects of UV radiation and oncogenic HPV infections in the development of NMSCs in immunocompetent individuals. However, there is limited evidence that UV exposure can reduce the efficacy of vaccination.

In a large, Dutch case–control investigation on UV exposure and immune response to vaccination, study subjects were vaccinated with the recombinant hepatitis B vaccine following five consecutive days of whole body UV irradiation (Sleijffers et al. 2001). Only those study subjects with a particular interleukin 1B polymorphism showed significantly suppressed antibody responses to hepatitis B virus vaccine, if exposed to UV irradiation prior to vaccination (Sleijffers et al. 2001).

In a 2011 review article, Norval and Woods reviewed studies on UV-induced immunosuppression and the efficacy of vaccination, and described a limited number of animal and human models of vaccination that did demonstrate UV-induced reduction in the efficacy of vaccination (Norval and Woods 2011). The authors recommended further evaluation of the role of UV radiation-induced immunosuppressive effects on the efficacy of certain vaccinations and noted that both the primary and delayed immune responses to several antigens, including microbial antigens, could be reduced by UV radiation exposures (Norval and Woods 2011).

1.02.4.8 Adverse Health Effects of Excessive Ultraviolet Radiation in Children

Worldwide, the burden of environmental disease is significantly greater for children than adults, especially for children under 5 years of age (Pronczuk and Surdu 2008). Unlike adults, children are often exposed to multiple environmental threats simultaneously, such as high UV index and ozone alerts that are often combined with other behavioral, social, and economic risk factors (Pronczuk and Surdu 2008). Environmental risk factors including climate, ozone depletion, air pollution, deforestation, and desertification have been estimated to contribute more than 33% of the disease burden in children worldwide (Pronczuk and Surdu 2008). Environmental factors contribute 36% to all deaths and 34% to the overall disease burden in children between 0 and 14 years of age (Pronczuk and Surdu 2008). The major health risks in children that are magnified by environmental threats include (1) diarrheal diseases and malnutrition (1.6 million deaths per year), (2) acute upper respiratory infections (1 million deaths per year), and (3) malaria (1 million deaths per year) (Pronczuk and Surdu 2008).

In the United States, one-third of residents report at least one sunburn per year (Hall et al. 2003). Sunburn is the adverse health effect most commonly experienced by children every year due to excessive UV-B exposure from stratospheric ozone depletion (Hall et al. 2003). Fair-skinned people are the most susceptible to sunburn and will run a correspondingly higher risk of long-term adverse effects, especially skin cancers. In children, skin cancer risks associated with UV exposures are greater for melanomas than for NMSCs (Westerdahl et al. 1994).

Major risk factors for melanoma include solar exposures to UV-A and UV-B with three or more blistering sunburns before 20 years of age (Holman and Armstrong 1984; Centers for Disease Control and Prevention 2011; Westerdahl et al. 1994). Since 80% of major sun overexposures occur before the age of 18 years, children are at the greatest risk of developing melanomas as young adults (Centers for Disease Control and Prevention 2011). Children who have suffered blistering sunburns are five times more likely to develop melanomas as young adults than children who have never had sunburns (Centers for Disease Control and Prevention 2011). Melanoma is now the most commonly increasing malignancy worldwide and is the most common cancer among people 25–29 years of age (Holman and Armstrong 1984; Centers for Disease Control and Prevention 2011; Narayanan et al. 2010; Diepgen and Mahler 2002). Melanoma kills about 100 000 people each year, 7000 in the United States (Holman and Armstrong 1984;

Centers for Disease Control and Prevention 2011; Narayanan et al. 2010; Diepgen and Mahler 2002).

In addition to increased melanoma risks from UV radiation, children are at a greater risk for recurrent upper respiratory infections than adults from combinations of the damaging effects of ozone on airways and UV-induced immunosuppression. High ozone levels can cause exacerbations of asthma and other reactive airway diseases that are prevalent in childhood, such as bronchiolitis and tracheobronchitis or croup. Viral infections with skin phases, such as HSV (cold sores) and papilloma (warts), are also more prevalent in children than in adults and can be reactivated by UV exposures (Ichihashi et al. 2004; Akgul et al. 2006).

In 2005, Hrushesky and coinvestigators in the Netherlands reported an unanticipated seasonal fluctuation in the frequency of cervical smears positive for oncogenic, anogenital HPV types during the summer months of highest solar UV exposures, with a peak in August (Hrushesky et al. 2005, 2006). The investigators concluded that UV-induced immunosuppression could be an important contributor to the increase in active HPV infections of the cervix during the summer months in addition to unprotected sex among adolescents and young adults during summer vacations (Hrushesky et al. 2005, 2006). Although this single reported association between summertime UV exposures and cervical HPV infections has not been confirmed and is confounded by multiple behavioral risk factors, the importance of this finding for young adults is that sexually transmitted infections with the high-risk anogenital HPV types are often acquired at early ages and are estimated to cause fatal anal and cervical cancers in over 500 000 young women worldwide every year (Hrushesky et al. 2005, 2006).

The last potential adverse health impact of excessive UV irradiation in children could be on the reduced efficacy of primary and booster series vaccinations for the most common viral infectious diseases of childhood, especially measles (Sharma et al. 2004). Measles is of the greatest concern because of its ease of airborne transmission, exacerbation by malnutrition and vitamin deficiencies (especially vitamin A), frequently devastating (blindness) or fatal outcomes in unvaccinated children, and high prevalence among displaced and overcrowded populations (Sharma et al. 2004). In 2004, Sharma and colleagues investigated an outbreak of measles in a city in India and observed that one-third of the cases had occurred in children who had previously been vaccinated against measles and who should have been protected (Sharma et al. 2004). The authors concluded that the virus-specific immunity could have waned in the vaccinated children who contracted measles because of solar UV-induced immunosuppression, although immunological evidence was not presented to support their conclusion (Sharma et al. 2004).

1.02.5 Ecosystem Effects of Excessive Ultraviolet Radiation

Excessive UV radiation from stratospheric ozone depletion has had significant adverse effects on both marine and terrestrial ecosystems, with significant implications for the aquatic food chain, marine fisheries, agricultural soil quality, and agricultural crop productivity. Plants are important components of both marine (phytoplankton, cyanobacteria) and terrestrial ecosystems and depend on solar UV radiation to catalyze the photochemical production of oxygen by photosynthesis (Caldwell et al. 2007). With the exception of motile phytoplankton, most plants cannot escape from UV radiation. Unlike animals and humans, plants have reduced capacities to produce subsurface melanin-like, UV-absorbing chemicals to protect themselves from excessive UV radiation. The adverse impact of UV irradiation on marine and terrestrial ecosystems has been studied extensively in environmental sentinel organisms since the 1970s when CFCs were first recognized as substances that deplete stratospheric ozone. Sentinel animals closely studied in terrestrial ecosystems have included earthworms and amphibians (frogs, salamanders) as surrogates for soil and freshwater ecosystem health, respectively (Misra et al. 2005; Blaustein and Johnson 2003; Ballaré et al. 2011; Lamare et al. 2011). Sentinel animals closely studied in marine ecosystems have included the echinoderms (sea urchins, sand dollars) and other invertebrates and larval fish as surrogates for the health of the marine food chain and commercial marine fisheries (Misra et al. 2005; Blaustein and Johnson 2003; Ballaré et al. 2011; Lamare et al. 2011; US Environmental Protection Agency, 2011).

1.02.5.1 Effects of Ultraviolet Radiation on Terrestrial Ecosystems

The damaging effects of excessive UV-B radiation on plants occur by direct damage to leafy vegetation and indirect damage by bio-geochemical deterioration of soil oxygenation and quality. Excessive solar UV exposures can directly burn, desiccate, discolor (silver leafing), and kill leaves and limit photosynthesis and plant growth (Caldwell et al. 2007; Ballaré et al. 2011). Indirect damage from UV radiation can create soil sinks of primary (carbon monoxide) and secondary photochemical (ozone) air pollutants, reducing soil oxygenation, altering nutrient distribution, limiting plant growth, and disrupting biological synchronization during critical developmental stages (Caldwell et al. 2007; Ballaré et al. 2011). The cascading effects of these excessive UV-induced adverse effects on agriculturally important plants include reduced resistance to plant pathogens, alternating growth spurts and stunts, and an inability to maintain competitive balance against insect pests and noxious weeds (Caldwell et al. 2007; Ballaré et al. 2011).

As noted, earthworms and amphibians have now been identified as sensitive monitors of the adverse effects of excessive UV radiation on terrestrial ecosystems for several reasons (Misra et al. 2005). Earthworms are the sentinels of soil pollution because they represent 80% of the total biomass of all soil invertebrates and their skin is permeable and contains several UV-sensitive sterols similar to the cholesterols in human skin that are precursors for active vitamin D (Misra et al. 2005). Frogs are the sentinels of air and freshwater pollution because they also have permeable skins, lay eggs without shells, and live in freshwater ecosystems with their large eyes constantly seeking prey and absorbing UV radiation (Blaustein and Johnson 2003).

Misra and coinvestigators studied dose-related effects of solar UV radiation on the earthworm, *Metaphire posthuma*, by measuring the generation of reactive oxygen species (singlet oxygen molecules, superoxide anions, and hydroxyl radicals), the photooxidation of lipids, and histopathological changes in earthworm integument (Misra et al. 2005). The authors reported significant dose–response effects from increasing doses of solar irradiation on the generation of reactive oxygen species and lipid peroxidation by-products (Misra et al. 2005). In addition, significant histopathological anomalies including thickening, vacuolization, and hypertrophy of epicutaneous cells occurred when earthworms were exposed to solar irradiation for 1–2 h, while 3-h exposure periods caused subepicutaneous muscular degeneration (Misra et al. 2005). Continuous exposure to solar irradiation for more than 3 h was lethal for earthworms (Misra et al. 2005). The investigators concluded that the 2004 levels of UV radiation in sunlight could produce significant phototoxic effects in earthworms by photodynamic action and generation of reactive oxygen species (Misra et al. 2005). Increases in the amount of UV radiation in sunlight from stratospheric ozone depletion was even more damaging to the ultrastructural elements in earthworm skin and resulted in fatalities in a dose–response manner (Misra et al. 2005).

1.02.5.2 Case Studies in Ozone Depletion III: Explaining Frog Deformities

Frogs are sensitive, sentinel monitors of water quality because of their aquatic habitats, permeable skins, and unshelled eggs laid on water surfaces. As early as 1989, scientists had recognized that congenital limb deformities impaired amphibian survival and contributed to dramatic declines in freshwater frog populations (Blaustein and Johnson 2003). Scientists were concerned that the potential environmental risk factors affecting frog survival would soon begin to impact other animal species.

Between 1994 and 1998, Blaustein and Johnson demonstrated that exposure to UV radiation could kill amphibian embryos and larvae, cause serious eye damage in frogs, and induce various types of congenital anomalies in the bodies of both frogs and salamanders (Blaustein and Johnson 2003). Between 1996 and 1998, Johnson and coinvestigators continued their amphibian deformity studies in broad surveys of California wetlands and discovered that the ponds filled with frogs with abnormal limbs were also infested with aquatic snails infected with a flatworm, *Ribeiroia ondatrae* (Blaustein and Johnson 2003). The infective cysts of the flatworms were found densely clustered below the skin at the base of deformed hind legs in the tree frogs living in the parasite-infested ponds (Blaustein and Johnson 2003). The investigators then experimentally infected other tree frogs with the same parasites, which developed similar hind limb deformities (Blaustein and Johnson 2003). The scientists concluded that immune system suppression from UV irradiation was responsible for opportunistic parasitic infections in frogs and significantly associated with extra, missing, or deformed hind legs (Blaustein and Johnson 2003). Other observed deformities included congenital blindness and skin defects that were not associated with parasitic infections and were also attributed to UV radiation overexposures (Blaustein and Johnson 2003). The significant human health impact of diseased and declining frog and other amphibian populations in freshwater wetlands as a result of increased UV radiation will be a significant loss of effective biological controls of arthropod vectors of infectious diseases, especially mosquitoes—highly competent vectors of viral (dengue, Chikungunya, yellow fever, Japanese encephalitis, and other encephalitides), protozoal (malaria), and parasitic (filariasis) diseases.

In summarizing the effects of solar UV radiation on terrestrial ecosystems, Ballaré and coinvestigators highlighted the following four key points (Ballaré et al. 2011). (1) The effects of UV-B on the growth of terrestrial plants are relatively small and, because the Montreal Protocol has been successful in limiting ozone depletion, the reduction in plant growth caused by increased UV-B radiation in areas affected by ozone decline since 1980 is unlikely to have exceeded 6%. (2) Solar UV-B has large direct and indirect (plant-mediated) effects on canopy arthropods and microorganisms. Therefore, trophic interactions (herbivory, decomposition) in terrestrial ecosystems appear to be sensitive to variations in UV-B irradiance. (3) Future variations in UV radiation resulting from changes in weather patterns and land use may have more important consequences on terrestrial ecosystems than the changes in UV caused by ozone depletion. This is because the resulting changes in UV radiation may affect a greater range of ecosystems, and will not be restricted solely to the UV-B component. (4) Several ecosystem processes that are not particularly sensitive to UV-B radiation can be strongly affected by UV-A (315–400 nm). One example is the physical degradation of plant litter. Increased photodegradation (in response to reduced cloudiness or canopy cover) will lead to increased carbon release to the atmosphere via direct and indirect mechanisms. (Ballaré et al. 2011).

1.02.5.3 Effects of Ultraviolet Radiation on Aquatic Ecosystems

Although UV radiation is gradually attenuated by the depths of the marine water column, UV-A and UV-B radiation can penetrate to depths of greater than 16 m (10% of surface UV-B) and 46 m (10% of surface UV-A) and exert significant impact on marine organisms (US Environmental Protection Agency 2011; Lamare et al. 2004). The effects of UV radiation have been studied on several marine species including phytoplankton, cyanobacteria, echinoderms and other invertebrates, and fish (Smith et al. 1992, Lamare et al. 2011, 2004; US Environmental Protection Agency 2011; Singh et al. 2010; Dahms and Lee 2010; Perotti and del Carmen Disguez 2006).

Phytoplankton are the foundation of the marine food chain and are restricted to the upper marine water column, the euphotic zone, where there is enough solar radiation to support photosynthesis and plankton productivity. Although most of the movements of phytoplankton are influenced by the physical actions of currents, tides, and waves, phytoplankton are also capable of active movement and positioning sensing to enhance their productivity and survival. Scientific investigations have demonstrated that UV-B irradiation can affect both the motility and the orientation mechanisms of phytoplankton in the euphotic zone, resulting in reduced productivity and survival rates (US Environmental Protection Agency 2011; Singh et al. 2010).

Solar UV-B radiation at current levels has also been found to damage the reproductive capacity and early developmental stages of echinoderms, crustaceans, and fish (Dahms and Lee 2010; Lamare et al. 2004; Perotti and del Carmen Disguez 2006). Small increases in UV-B exposures in marine ecosystems will further reduce productivity and survival of both phytoplankton and smaller marine creatures, reducing the size of the marine population that depends on these organisms for survival, with significant impact on commercial fisheries. The ultimate impact on humans would be a reduction in the availability of seafood proteins and cardioprotective omega-3 polyunsaturated fatty acids.

Like the phytoplankton, cyanobacteria that inhabit the euphotic zone of the marine water column are also capable of photosynthesis and participate in the marine food chain (Singh et al. 2010). UV radiation has both direct effects on cyanobacteria because of absorption by biomolecules and indirect effects by inducing oxidative stress with DNA damage (Singh et al. 2010). Cyanobacteria have, however, developed several effective strategies for defense against UV radiation, including not only avoidance behaviors similar to phytoplankton but also synthesis of UV-absorbing compounds such as the mycosporine-like amino acids and scytonemin (Singh et al. 2010). In addition, cyanobacteria can respond rapidly to UV-induced oxidative stresses by DNA screening and repair mechanisms or by programmed cell death (apoptosis) (Singh et al. 2010). In summary, the cyanobacteria are primitive prokaryotes that first appeared on Earth before there was a stratospheric ozone layer and may be key organisms to study in the development of new UV-absorbing compounds for broad-spectrum sunscreens because of their unique UV defenses (Singh et al. 2010).

The echinoderms are also ubiquitous in the marine environment, are long-lived, dominate the benthic macrofauna, and contribute to the marine food chain (Lamare et al. 2011). UV radiation negatively impacts echinoderms by causing DNA damage and mutations (Lamare et al. 2011). However, similar to the cyanobacteria, echinoderms have evolved defense strategies against UV radiation including UV-absorbing pigments (carotinoids, melanin, and mycosporine-like amino acids), antioxidants to counter oxidative stress, and DNA screening and repair mechanisms (Lamare et al. 2004, 2011; Singh et al. 2010). The echinoderms are motile like phytoplankton and also utilize avoidance behaviors to limit their UV radiation exposures (Lamare et al. 2004, 2011).

UV radiation can also cause cellular and molecular damage in fish despite defense mechanisms that include better avoidance behaviors and UV-absorbing pigments than echinoderms and phytoplankton (Perotti and del Carmen Disguez 2006). UV radiation impairs sperm motility, reduces fertility, interferes with embryo cleavage, and causes embryo and neonatal malformations that can threaten the sustainability of natural finfish populations (Perotti and del Carmen Disguez 2006). Perotti and Dieguez studied the health effects of enhanced levels of UV radiation in three species of Patagonian anurans in southern Argentina, an area near and often within the Antarctic ozone hole (Perotti and del Carmen Disguez 2006). Anuran fish were selected for the study because they are ubiquitous in shallow waters and breed during the austral spring when UV-B levels are the highest in the southern hemisphere (Perotti and del Carmen Disguez 2006). The researchers reported a UV dose–response increase in congenital malformations, but not in survivorship (Perotti and del Carmen Disguez 2006). The fish that received the highest levels of UV radiation also presented higher concentrations of UV-absorbing melanin, suggesting that solar UV exposure triggered photoprotection by pigments (Perotti and del Carmen Disguez 2006). Most marine species have developed behavioral, cellular, and molecular mechanisms to protect themselves from enhanced UV radiation, all of which deserve further study.

Although several studies have now demonstrated the negative impacts of UV-B radiation on both the primary aquatic food web producers (cyanobacteria, phytoplankton, macroalgae, and aquatic plants) and their consumers (zooplankton, crustaceans, amphibians, fish, and corals), Häder and coinvestigators have raised the following two important questions regarding the ultimate impact of solar UV-B radiation on carbon dioxide absorption and on species composition within aquatic ecosystems and on the interaction of organisms between the trophic levels within aquatic ecosystems (Häder et al. 2011). (1) Will a UV-B radiation-induced decrease in the population size of the more sensitive primary producers be compensated for by an increase in the population size of the more tolerant species yielding a net negative impact on the absorption of carbon dioxide by aquatic ecosystems? (2) Will there be a significant impact on the quantity and quality of nutrients cycling through the aquatic food web, including the generation of aquatic food proteins for humans?

1.02.6 Human Adaptive Strategies for Ozone Depletion and Excessive Ultraviolet Radiation

The most important adaptive strategies for people to adopt to protect themselves from excessive UV radiation from stratospheric ozone depletion are to protect their skin and eyes from sun damage by using and selecting proper sunscreens and wearing tinted eyeglasses (Table 5). The skin and eyes must be protected from both the sunburn effects of UV-B and the deeply penetrating effects of UV-A.

Today, most sunscreens are composed of combinations of organic chemicals to absorb UV light (padimate, oxybenzone), inorganic chemicals to filter and reflect UV light (titanium dioxide, zinc oxide), and newer organic particles to both absorb and reflect UV light (Parsol®, Tinosorb®, Uvinul®). Historically, sunscreens were developed for protection from sunburn from UV-B only. As a result of new federal regulations in the United States, sunscreens labeled as "broad spectrum" are protective for both UV-B and UV-A irradiation for a period of time (the sun protection factor (SPF)) before damaging sunburns. A sunscreen with an SPF of 15 properly applied (defined as $2\ \mathrm{mg\,cm^{-2}}$ (Molina and Rowland 1974) of sun-exposed skin) will protect one from 93% of UV-A and UV-B radiation; SPF 30 is protective against 97% of UV-A and B; SPF 50 is protective against 98% of UV-A and B. Table 7 lists some of the most common sunscreen ingredients stratified as either absorbents or physical filters/receptors used in broad-spectrum sunscreens that are protective in combined proprietary sunscreens against both UV-A and B.

1.02.6.1 Public Perceptions Regarding Safe Solar Ultraviolet Radiation Exposures

Ezzedine and coinvestigators have studied sun exposure behaviors in large subcohorts of survey-responding travelers, nontravelers, and expatriates nested in a larger cohort of 12 741

Table 7 The most common US Food and Drug Administration (FDA)-approved sunscreen ingredients used in broad-spectrum sunscreens

Sunscreen ingredients	*UV-A-1 range (340–400 nm) covered*	*UV-A-2 range (320–400 nm) covered*	*UV-B range (290–320 nm) covered*
UV absorbers in sunscreens			
Aminobenzoic acid (para-aminobenzoic acid (PABA))	−	−	+
Avobenzone	+	−	−
Cinoxate	−	−	+
Dioxybenzone	−	+	+
Ecamsule (mexoryl SX)	−	+	−
Ensulizole (phenylbenzimiazole sulfonic acid)	−	−	+
Homosalate	−	−	+
Menthyl anthranilate	−	+	−
Meradimate	−	+	+
Octocrylene	−	−	+
Octinoxate (octal methoxycinnamate)	−	−	+
Octal salicylate (octisalate)	−	−	+
Octocrylene	−	−	+
Oxybenzone	−	+	+
Padimate O	−	−	+
Sulisobenzone	−	+	+
Trolamine salicylate	−	−	+
Inorganic physical filters and reflectors			
Titanium dioxide	+	+	+
Zinc oxide	+	+	+

+, UV range canceled; −, UV range not canceled.

French adult volunteers enrolled in the SU.VI.MAX cohort and observed the following results (Ezzedine et al. 2007a,b; Autier 2009). (1) Women travelers reported more frequent sun exposures over the past year, sun bathed in high UV-index areas daily for more than 2 h, and experienced more intensive sun exposures than nontravelers (Ezzedine et al. 2007a) (2) Although the use of sun protection products was similar in all travelers and nontravelers, women used sunscreens with higher SPFs more often and more regularly than men (Ezzedine et al. 2007a).

In a similarly designed study, the same investigators sent sun exposure and sun protection behavior questionnaires twice to all subjects in the SU.VI.MAX cohort, with 1694 respondents reporting travel to a tropical or high UV-index country during their lifetimes for more than three consecutive months (expatriates) (Ezzedine et al. 2007b) The investigators described the following results (Ezzedine et al. 2007b). (1) Female expatriates reported more frequent deliberate sun exposures, more sunbathing between 11 a.m. and 4 p.m., less gradual sun exposure, more intensive sun exposures, more exposures during nautical sports, and more nude exposures than female nonexpatriates (Ezzedine et al. 2007b). (2) Male expatriates reported more frequent intensive sun exposures and more skin exposures during nautical and mountain sports than male nonexpatriates (Ezzedine et al. 2007b) In summary, Ezzedine and coinvestigators have now registered a large cohort of French adults to study for sun exposure and protection behaviors in tropical and high UV-index countries for short and prolonged stays, and their results have repeatedly demonstrated that travelers would benefit from more pretravel advice regarding sun exposures and sun protective behaviors (Ezzedine et al. 2007a,b; Autier 2009).

Other studies have now closely investigated public attitudes, knowledge levels, and behavioral practices regarding sunscreen use. In 2006, Autier reported sunscreen abuse by persons intentionally seeking to expose themselves to sunlight for excessively prolonged periods (Wright et al. 2001). Wright and coinvestigators evaluated the attitudes toward sunscreen effectiveness and found that 47% of study subjects reported staying out longer in the sun after applying sunscreen (Ezzedine et al. 2008). In 2008, Ezzedine and coinvestigators reported the results of a cross-sectional study on artificial and natural tanning behaviors in a French national cohort of 7200 adults (Autier 2009). The investigators determined that indoor tanners were also regular sunbathers unconcerned about the risks of combined indoor and outdoor UV exposures (Autier 2009). In a 2009 survey assessment of sunscreen knowledge, Wang observed that only 48.2% of survey respondents knew that “SPF” was the acronym for “sun protection factor” (Wang and Dusza 2009).

Regarding the proper application of sunscreens, quantity and frequency of use remain among the most important factors limiting sunscreen efficacy (Wang and Dusza 2009; Kullavanijaya and Lim 2005; Lim and Cooper 1999; Sunscreens: An Update 2008). The international standard quantity of sunscreen application used to determine SPF factors is 2 mg cm^{-2}. (Sunscreens: An Update 2008; Diffey 2001). However, Diffey observed that most people apply only 0.5–1.5 mg cm^{-2} of sunscreen and do not reapply sunscreens after swimming or excessive sweating (Diffey 2001). In summary, observational studies have now demonstrated that the public often abuses sunscreens for intentional UV overexposures and knows little about proper sunscreen protection, selection, and use (Ezzedine et al.

2007a,b, 2008; Autier 2009; Wright et al. 2001; Sunscreens: An Update 2008; Diffey 2001).

1.02.6.2 What Are the Most Effective Prevention Strategies for Protection from the Adverse Health Impact of Solar Ultraviolet Radiation?

The primary prevention strategies for protection from the adverse health impact of solar radiation include the following. (1) Limit exposure to UV radiation, especially between 10 a.m. and 4 p.m. (2) Wear sun protective clothing and UV-A- and UV-B-protective sunglasses. (3) Use sunscreens with an SPF of 15 or higher depending on your skin type. (4) Avoid all artificial tanning devices. (5) For children younger than 6 months of age, always use hats, clothing, and shading, rather than sunscreens. (6) Encourage all children to practice the shadow rule: seek shade whenever your shadow is shorter than you are tall.

The secondary prevention strategies for protection from the adverse health impact of solar radiation focus on screening and early detection of skin cancers and include the following. (1) Be aware of new skin lesions and practice frequent skin examinations. (2) Know the warning signs of melanoma or the ABCD rule (asymmetry, border irregularity, variable color, and diameter greater than 6 mm). (3) Seek immediate physician consultation for evaluation of any new or persistent skin marks or any changes in preexisting skin marks.

1.02.6.3 Eliminate SPF Confusion: Do You Know Your Skin Type and How to Select the Right Sunscreen?

The SPF is derived from a complex equation that calculates the amount of time it takes for UV radiation of various wavelengths to cause sunburn. In the simplest terms, the SPF is the amount of UV-B radiation required to cause sunburn on skin with sunscreen on as a multiple of the amount of time required to cause sunburn without sunscreen. In reality, several factors significantly affect the protective capabilities of the SPF number including amount of sunscreen applied, altitude, season of the year, time of the day, sweating, water exposure, reflection by snow or water surfaces, and, most importantly, skin type. Unfortunately, a very common misperception about the SPF is that if you get sunburned in 1 h, a sunscreen of SPF 15 will offer 15 h of protection. The six skin types, their definitions, and the recommended SPF for sunscreens appropriately applied by skin type are listed in Table 8. Sunscreens should always be broad-spectrum products that block both UV-A and UV-B rays, hypoallergenic, and noncomedogenic, so as not to cause rashes or clog pores, causing acne.

1.02.6.4 Do Sunscreens Really Prevent Skin Cancers?

Randomized controlled trials have now demonstrated that regular sunscreen use can prevent the development of AK (Thompson et al. 1993). Since AK are precursors of SCCs, sunscreens can prevent the development of SCCs (Thompson et al. 1993). The regular use of sunscreens may also prevent melanomas (Green et al. 2011).

1.02.6.5 Case Studies in Ozone Depletion IV: Preventing Melanomas with Regular Sunscreen Use

In 2011, Green and coinvestigators in the subtropical region of Nambour, Queensland, Australia, provided conclusive evidence from a randomized controlled trial that the regular use of sunscreens prevented melanoma (Green et al. 2011). Their study included 1621 adults randomized to regular (daily) sunscreen use ($n = 812$ persons) or to discretionary use ($n = 809$ persons), which included no sunscreen use at all (Green et al. 2011). The daily- and discretionary-use groups were well matched for skin types, nevus density, sunburn and skin cancer history, and outdoor and sun protective behaviors (Green et al. 2011). The daily users applied sunscreen with an SPF of 16 every morning to the head, neck, arms, and hands and reapplied sunscreen after sweating, bathing, or long sun exposures (Green et al. 2011). The authors found that the daily application of a broad-spectrum sunscreen with an SPF of 16 during a 5-year treatment period reduced the incidence of new primary melanomas during a subsequent 10-year follow-up period (Green et al. 2011). Ten years after trial cessation, 11 new primary melanomas were identified among the daily sunscreen group compared with 22 melanomas among the discretionary group ($p = .051$) (Green et al. 2011). The reduction in invasive melanoma incidence was even more substantial with 3 invasive melanomas in the daily-use group compared to 11 in the discretionary group ($p = .045$) (Green et al. 2011).

Although the Green et al. study supported the hypothesis that daily sunscreen use prevented CMM, the study prompted an immediate series of subsequent editorials that challenged the significance and the external validity of the reported findings. The major limitations of the study were identified as (1) low statistical power to detect significant differences if present, (2) variable interpretations of CMM invasiveness by many pathologists, (3) selection of less rigid test statistics, (4) unblinded investigators, (5) exclusions of CMMs on the trunk and the extremities, (6) limited applications to populations other than the light-skinned Australians of Nambour, and (7) the borderline significance of p-values near .05 (Gimotty and Glanz 2011; Golderhersh and Kowlowsky 2011; Doré 2011).

Table 8 Know your skin type and select the right sunscreen

Skin type	*Skin color (other common descriptors)*	*Sun exposure effects*	*Recommended sunscreen SPF*
I	White (Celtic or albino, freckles common)	Always burns, never tans	30+
II	Light (European)	Always burns, rarely tans	30+
III	Light-intermediate or beige (dark European)	Sometimes burns, sometimes tans	15+
IV	Olive or beige with brown tint (Mediterranean)	Tans easily, burns less	15+
V	Brown	Tans easily, rarely burns	15+
VI	Black	Does not burn	15+

Courtesy Fitzpatrick scale.

1.02.7 Mitigation Strategies for Stratospheric Ozone Depletion

The most successful climate mitigation strategy, aimed at preserving the ozone layer, is the Montreal Protocol on Substances that Deplete the Ozone Layer, the Vienna Convention for the Protection of the Ozone Layer, and public–private partnerships, such as the Green Chill Advanced Refrigeration Partnership and the Responsible Appliance Disposal (RAD) Program in the United States. All 196 UN nations in the world have now ratified the Montreal Protocol and the Vienna Convention, making these two international treaties the first and only treaties in the world to achieve universal ratification. At the Nineteenth Meeting of the Parties to the Montreal Protocol in September 2007, all party nations agreed to more aggressively phase out the ozone-depleting hydrochlorofluorocarbons (HCFCs), early substitutes for the CFCs in widespread use today as refrigerants, solvents, and insulators. The agreement to adjust the phase-out schedule for HCFCs is expected to reduce atmospheric emissions by 47%, compared to earlier commitments, and for the developing nations, the agreement would result in a 58% reduction over 30 years. The climate effects of stronger HCFC phase-out commitments would depend on technological choices to replace the HCFCs and have been estimated to represent a phase-out of more than 9000 metric tons of carbon dioxide equivalent emissions over 30 years, or the equivalent of removing the automotive emissions of 55 million US passenger cars (40% of the US national passenger car fleet) each year for the next 30 years. The most significant outcomes of the international treaties to protect the ozone layer and the world's climate have been to send clear signals to world markets about the needs to develop new alternatives for ozone-depleting substances that do not harm the ozone layer or other aspects of the climate system.

Public–private partnerships also offer successful mitigation strategies for limiting ozone depletion and resulting alterations in climate patterns. The Green Chill Advanced Refrigeration Partnership is a US EPA cooperative alliance with the supermarket industry and other stakeholders to promote advanced technologies, strategies, and practices that reduce the amount of refrigerants used in equipment and released into the atmosphere. In 2007, Green Chill partners reduced emissions of ozone-depleting refrigerants by 30 metric tons and greenhouse gas emissions by 2.5 million metric tons of carbon dioxide equivalents, or the equivalent of avoiding the emissions of 0.5 million passenger cars in 1 year.

The RAD Program is another US EPA voluntary public–private partnership with retailers, utilities, universities, municipalities, and manufacturers to responsibly dispose of appliances that use ozone-depleting substances as refrigerants and insulators, primarily freezers and refrigerators. The partners in the RAD Program have achieved substantial benefits for the ozone layer and for climate by using best practices to ensure that all refrigerants and insulating materials are recovered or destroyed properly. In 2008, RAD partners disposed of more than 1 million refrigerant-containing appliances and reduced greenhouse gas emissions by over 4 million metric tons of carbon dioxide equivalents, or the equivalent of avoiding the emissions of 0.92 million passenger cars in 1 year.

1.02.7.1 The Public Health and National Financial Burdens of Skin Cancers: Recommendations for Policymakers

Skin cancer is the most common cancer in the United States and in several other nations, such as the United Kingdom, Australia, and New Zealand (Guy and Ekwueme 2011). Skin cancer is costly to treat in advanced stages, places significant financial burdens on national health care delivery systems, and results in significant losses in productivity and quality of life. Recently, Guy and Ekwueme conducted a meta-analysis of the world's peer-reviewed literature on the years of productive life lost (YPLL) and the indirect costs of melanoma and NMSCs in the United States (Guy and Ekwueme 2011). The investigators identified 16 relevant studies meeting their inclusion criteria, 6 from the United States and 10 from other industrialized nations (Guy and Ekwueme 2011). The mean number of YPLL per death from skin cancer was 15 years for melanoma and 10 years for NMSCs (Guy and Ekwueme 2011). The indirect costs attributable to melanoma and NMSCs ranged from $US28.9–39.2 million for morbidity to $US1.0–3.3 billion for mortality, respectively (Guy and Ekwueme 2011). The authors concluded that skin cancers led to significant increases in YPLL and indirect costs associated with premature morbidity and mortality and recommended greater governmental support of prevention and detection programs to reduce the prevalence of skin cancers, to improve national productivity, and to reduce the cost burdens on health care systems (Guy and Ekwueme 2011).

Skin cancer diagnoses and treatments represent the single-most costly burden to the national health care systems of Australia and New Zealand (Guy and Ekwueme 2011; Brougham et al. 2010). As a result of the excessive economic burden of skin cancer on health care delivery systems, nations have developed several innovative programs to improve early detection and treatment of skin cancers including targeted screening of high-risk populations and phototriage for early referrals for skin cancer diagnoses and treatments (Swetter et al. 2003; Morton et al. 2011; McCarthy 2004).

In 2004, Swetter and coinvestigators with the US Veterans Administration designed a targeted skin cancer screening program for high-risk US veterans with minimal to no prior dermatologic care (Swetter et al. 2003). The investigators reported that of 374 patients (362 men, 12 women, mean age 63.4 years) screened for skin cancers in California over a 3-year period, 54% ($n = 203$) had a positive screen, including 139 with presumptive actinic keratosis, 41 with BCC, 9 with SCC, and 14 with dysplastic nevus versus melanoma (Swetter et al. 2003). The investigators concluded that targeting a high-risk population of predominantly elderly, Caucasian men yielded high detection rates of premalignant and malignant skin lesions and resulted in more efficient referrals for definitive treatment of premalignant conditions and skin cancers in early stages (Swetter et al. 2003).

Recently, Morton and coinvestigators in the United Kingdom conducted an observational study to compare the utility and cost-effectiveness of conventional versus phototriage referral pathways for presumptive skin cancers (Morton et al. 2011). Phototriage meant that patients would initially be sent to medical photographers in community health centers for high-quality photographs and dermatoscopic images of skin lesions to be later reviewed by dermatologists for referrals (Morton et al. 2011). Phototriage permitted 91% of patients (263/289) to achieve definitive care at their first visit to either a community or specialty treatment center compared with only 63% (117/186) via the conventional referral pathway (Morton et al. 2011). The mean waiting time to definitive treatment was reduced on the phototriage pathway; there was a 72% reduction in referrals to specialty clinics, freeing up capacity; and, despite the costs of photography, there was a cost saving of £UK1.70 per patient using phototriage (Morton et al. 2011).

Policymakers are encouraged to support both primary and secondary prevention programs for skin cancer because skin cancers place significant burdens on national productivity and health care delivery and costs. Primary and secondary prevention programs should be targeted at decision makers and high-risk groups. For example, primary prevention programs, such as Australia's "Slip, Slop, Slap, Seek, and Slide" program, targeted at the parents of young children and adolescents have resulted in greater public awareness of the risks of UV irradiation and skin cancer and a reduction in deaths from melanomas in regular sunscreen users (McCarthy 2004). Screening programs targeted at elderly, fair and light-skinned persons who have minimal to no prior dermatologic care are successful in detecting skin cancers at earlier stages when the costs of definitive treatment are less (Swetter et al. 2003). Lastly, innovative technologies, such as telemedicine and phototriage, can also improve screening for skin cancer, result in earlier referrals for definitive treatment, and reduce health care costs while freeing up capacity in specialty clinics (Morton et al. 2011).

1.02.7.2 Case Studies in Ozone Depletion V: "Slip, Slop, Slap, Seek, and Slide"

Australia receives 15% more solar UV radiation than equivalent locations in the northern hemisphere and has the highest incidence rates for skin cancers in the world, with 2002 age-standardized incidence rates for BCC of 1150/100 000, for SCC of 560/100 000, and for melanoma of 40/100 000 (McCarthy 2004). As a result, Australia has developed highly successful primary prevention programs for skin cancer awareness initially focused on sunscreen use with a reduction in melanoma deaths and currently refocused on sun avoidance and targeted at the highest risk groups for lifetime UV exposures, children, and adolescents. As in other nations, primary prevention programs in Australia are often based on state and nongovernmental organization partnerships.

In the 1980s, the Victoria Anti-Cancer Council, an affiliate of the Australian Cancer Council, launched the "Slip, Slop, Slap" program, meaning "*Slip* on a shirt, *Slop* on sunscreen, *Slap* on a hat, *Seek* shade, and *Slide* on sunglasses" (McCarthy 2004). The program was targeted at school-age children and adolescents, presented in multiple media formats from cartoons to radio and televised public messages, and was often promoted at beachfronts and sporting events. Since then, all other states in Australia have adopted similar skin cancer prevention programs with the clear message of "sense in the sun" as being compatible with the Australian environment and an outdoor lifestyle (McCarthy 2004). Although adolescents remain more resistant than younger children to "sense in the sun" campaigns in Australia and elsewhere, the success of "Slip, Slop, Slap, Seek, and Slide" programs has resulted in "no hat, no play" policies at schools and behavior modification by the parents of children under 10 years of age, now more likely to be seen on Australian beaches wearing hats and *Rash* shirts (tight mesh fabric shirts that remain on the wearer while in the water) (McCarthy 2004).

1.02.8 Conclusions

This chapter has addressed the factors influencing ozone levels in the atmosphere, the beneficial as well as the detrimental effects of UV radiation in man, and the environmental impact of increased UV radiation. In addition, this chapter has relied on actual case studies in stratospheric ozone depletion and excessive UV exposures in high-risk human and animal populations to describe the impact of UV radiation on human and animal health and immune status, and on aquatic and terrestrial food chains and ecosystems.

Sunbathing and other outdoor pursuits will continue to remain popular activities among residents of and travelers to temperate and tropical destinations worldwide despite the associations between excessive UV exposures and skin cancer. Health care providers should counsel families about photoprotection while outdoors and encourage everyone to take advantage of recent advances in the development of more effective broad-spectrum sunscreens and even photoprotective clothing for themselves and their children.

Although the historical ozone-depleting substances have been identified and controlled, CFC substitutes and their future replacements, such as the bromofluorocarbons and the fluoroolefins, cannot restore lost stratospheric ozone; some will further deplete stratospheric ozone for some time, and all will augment greenhouse gas effects and their secondary photochemical pollution effects in the troposphere (Tang et al. 2011). The time line to ozone layer repletion cannot be accurately predicted and will likely approach restoration slowly and asymptotically, despite new mitigation strategies and policy changes. Nevertheless, several innovative and successful strategies to reduce the adverse human health and ecosystem effects of ozone depletion have now been proposed, tested in prospective investigations, implemented nationally, and should be adopted and supported by world policymakers.

Glossary

asset any item of value that potentially is exposed to hazards; can include buildings, other infrastructure, human beings, public health, ecosystems, etc.

coastal zone the potentially wide area between the dry land above the littoral and the shelf margin.

hazard a potentially harmful event.

local sea level the vertical distance between the sea surface and land surface.

global sea level the global average of local sea level

resilience the ability of a system to absorb disturbance while retaining its basic function and structure

risk the probability that a hazardous event will cause a certain damage to an asset.

vulnerability characteristic of an asset to experience damage if exposed to a hazard.

1.03.1 Introduction

Considerable work has been published on the impact of climate variability and climate change on human health (e.g., Patz et al. 2005; McMichael et al. 2006; Karl et al. 2009). However, besides a few exceptions (e.g., Nicholls et al. 2007a; Craig 2010), the question of how local sea-level rise (LSLR) may impact human health surprisingly has not received the same level of attention. Mostly, focus has been on the direct impacts of sea level-related disasters, whereas the impact of a slow rise in sea level on human health has received little attention. While there are many challenges to predicting or projecting future LSLR, even a seemingly small increase in sea level can have a dramatic impact on many coastal environments (e.g., Titus 1990). There are a number of 'domino effects' potentially triggered by LSLR that can impact human health in various ways. Storm surges amplified by LSLR would lead to more severe impacts on health infrastructure. Hurricane Katrina in 2005 demonstrated the damage of flooding to health infrastructure at a time when more health infrastructure was needed. In London, 16 hospitals are in the Thames estuary at high flooding risk (Reeder 2010), and a storm surge exceeding the capacity of the Thames Barrier would put this infrastructure at risk. In many coastal areas, potentially polluting infrastructure is exposed to inundation. For examples, in the Galveston area in the United States, an LSLR of 0.69 m could inundate or impact a total of 23 waste treatment or holding facilities (Yoskowitz et al. 2009). Ten of these sites are wastewater treatment plants; five of them contain industrial and hazardous waste; and three sites (so-called superfund sites) are highly contaminated. An inundation of these sites would lead to a high risk for the population, through reduced water and air quality, soil contamination, and pollution of coastal waters.

The impacts of LSLR and coastal protection on ecosystems (Plag and Jules-Plag 2012) also potentially could impact water and air qualities. In many regions, where coastal ecosystems are important resources for the local economy, LSLR might reduce access to these resources and thus impact the socioeconomic fabric of the local settlements.

Coastal erosion is a serious issue in many coastal areas, which has the potential to increase the local socioeconomic impacts. For example, most of the West African coasts are experiencing significant coastal erosion, and climate change and LSLR are expected to increase this trend (ACCC 2006). Coastal erosion in Lagos, the largest city in Nigeria, which on average is less than 2 m above current sea level, could rapidly move the coastline into the city. A similar situation exists for Shanghai, the largest city in China.

The possibility of a rapid LSLR in many coastal regions is increasingly recognized. It also needs to be emphasized that a rapid global sea-level rise (GSLR) is a new challenge for our civilization: never before in modern human history, with major built environments in the coastal zone, have humans been faced with a significant GSLR (Rowley et al. 2007; Orbach 2010). During the last deglaciation, rapid changes in local sea level (LSL) altered coastlines within decades. However, during that time, large-scale built environment was absent, and with much lower populations, human beings could easily adopt to shifting coastlines. Today, there is substantial built environment and crucial infrastructure in coastal zones, and urbanization of the coastal zone continues to increase. Over 600 million people live in coastal areas that are less than 10 m

http://dx.doi.org/10.1016/B978-0-12-384703-4.00105-2

above LSL, and a large fraction of these areas can be impacted even by a small LSLR through increased inundation during storm surges. Two-thirds of the world's cities with populations over five million are located in these areas. Under these conditions, rapid changes in coastlines and increased inundation risks during storm surges would be devastating both economically and environmentally.

Adaptation and mitigation is insurance against the risk of impacts of a hazard on lives and property, including impacts on human health. For informed decision, a detailed analysis of the risk needs to take place. Crucial ingredients for risk assessments are hazard analysis, an accepted basis for determining the value of the assets potentially exposed to the hazards, and a quantitative understanding of the vulnerability of the assets to the hazards. In the following, the terminology used here for the risk-based approach to potential health impacts of LSLR is first summarized (see Section 1.03.2). A more detailed description of the methodology is given in Plag and Jules-Plag (2012). Sea level-related hazards that might impact human health directly or indirectly, including their probability density functions (PDFs), are considered next (see Section 1.03.3), followed by the assets that may be exposed to these hazards and their vulnerability (see Section 1.03.4). Finally, the authors discuss adaptation and mitigation measures to reduce the risk (see Section 1.03.5) and give recommendations to decision makers (see Section 1.03.6).

1.03.2 Risk-Based Approach to the Impact of Sea-Level Rise on Human Health

In assessing the impact of coastal LSLR on human health, the authors take a risk-based approach (Plag and Jules-Plag 2012). The concept of vulnerability to natural hazards, including climate variability, climate change, and climate change impacts, is a relatively new one, and a common language still needs to be developed (e.g., Dolan and Walker 2003). Different disciplines use different approaches with different terminologies. Therefore, the authors briefly introduce their approach, which is derived from an insurance approach. Risk is defined as the product of hazard probability times vulnerability of exposed assets times the value of the assets. The mathematical details are given in Plag and Jules-Plag (2012).

The probability of the hazard states the likelihood of a hazard of intensity I occurring during a time interval T. This probability may be time dependent. For example, at a given location x the probability of a storm surge exceeding a certain height (e.g., 3 m) within, e.g., 500 years, may change because of climate change impacting the frequency and intensity of storm surges or because of changes in the mean sea level. Thus, a risk-based approach will have to use realistic estimates of future probabilities. For many natural hazards, the PDF can be determined based on past occurrences of the hazard. However, climate change can be expected to change the PDF of climate-related hazards. Under these conditions, the past may be a poor analog for the future. In order to achieve realistic risk estimates, including the uncertainties of these estimates, the potential change in the PDF of the climate-related hazards has to be kept in mind.

Assets can be anything from a building or service infrastructure, human population, and ecosystems to natural resources such as groundwater, fishing grounds, and beaches for tourist activities. Health services are also among the assets and so is the general state of public health in an area. Assigning value to the various assets in the coastal zone can be difficult. While the economic value of the built environment is relatively easy to determine, the value of human conditions and resources, human services, and ecosystem services is far more difficult to agree upon.

Assessing the vulnerability of assets also poses a wide range of challenges. For built structures, the vulnerability to natural hazards can be estimated based on knowledge of the materials' capacity to tolerate hazardous environmental conditions and the structural capacity to withstand environmental loads. Vulnerability of socioeconomic systems is far more difficult to assess, particularly if there are hidden thresholds that can lead to a collapse of the system. Likewise, determining vulnerability of ecosystems is difficult because of thresholds that are often not known. Vulnerability of health services to direct impacts of natural hazards and indirect impacts of the socioeconomic consequences of the hazards are difficult to quantify. The concept of resilience of these services to environmental, social, and economic disturbances can be an alternative to the risk-based approach.

1.03.3 Sea-Level Hazards

Coastal sea-level hazards include waves, currents, storm surges combined with tides, and slow inundation. These hazards can be exacerbated through slow changes in mean LSL. LSL is defined as the distance from the sea surface to the land surface. LSL changes whenever the sea surface height or the land surface height changes. At any coastal location, LSL is the result of many processes acting on local to global scales in space, and from instantaneous to millions of years in time. A complete overview of the processes impacting LSL is provided by Plag (2006) and Plag and Jules-Plag (2012).

In many coastal regions, the PDF of sea-level hazards can be determined based on long LSL records obtained by tide gauges (Tawn and Vassie 1989; Batstone et al. 2009), although multidecadal climate variability can lead to biased attributions (Donner 2102). Changes in the PDF of the sea-level hazards can result from two contributions: (1) the hazard (waves, currents, storm surges) itself may change in its frequency and intensity because of dynamic changes in the ocean/atmosphere system; and (2) the impact of the hazard may change because of a change in mean sea level. Figure 1 illustrates this interaction of slow, mediocre changes in mean conditions with possible changes in the extremes for the case of storm surges. With rising sea levels, storm surges will lead to increased and more frequent inundation of wetlands and lowlands, exacerbated coastal flooding, and eventually permanent submersion. LSLR will alter tidal ranges in rivers and bays, increase the heights of waves relative to land, and increase the salinity of estuaries and aquifers and impair water quality. Storm surges and waves will also erode shorelines more rapidly. LSLR will lead to changes in the locations where rivers deposit sediment and decrease the amount of light reaching the bottoms.

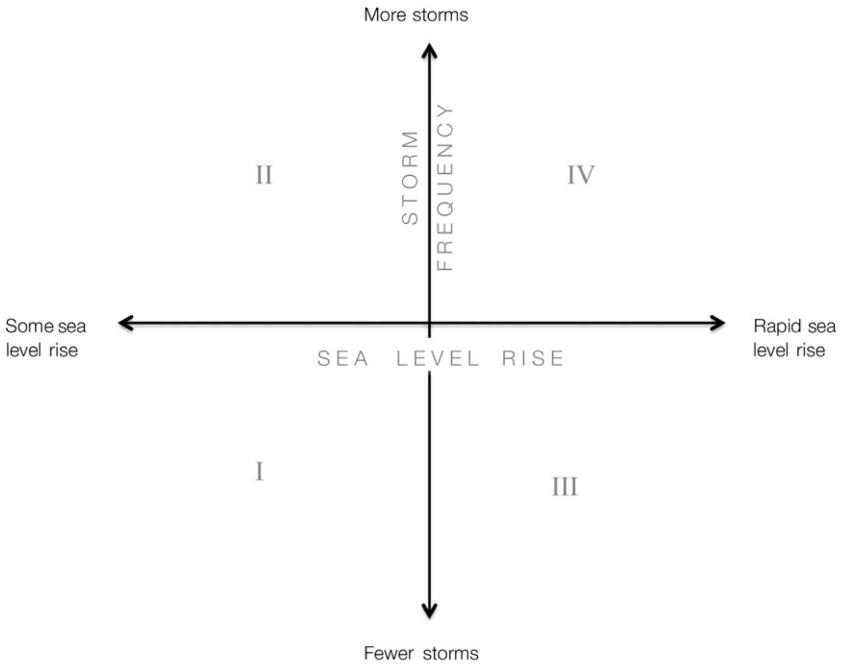

Figure 1 Impact of LSLR and storm surge frequency on hazard probability. A small LSLR and fewer storms (I) will not lead to any significant change in storm surge probability. However, even a small LSLR and more storms (II) would significantly increase the probability of a storm surge and inundation. Fewer storms combined with a rapid LSLR (III) would lead to less frequent but more intense storm surges and impact the higher end of the PDF. The most severe change in inundation risks result from more storms combined with a rapid LSLR (IV).

Considering the high sensitivity of the PDF of sea-level hazards to sea-level changes, it is mandatory to have an understanding of the PDF of LSL changes. Over the past two decades, an increasing number of GLSR and risk assessments have been carried out on national and international bases (e.g., Warrick and Oerlemans 1990; Warrick et al. 1996; Church et al. 2001; Hulme et al. 2002; Lowe and Gregory 2005; Anthoff et al. 2006; Plag et al. 2006; Tol et al. 2006; Rowley et al. 2007; Jacob 2007; CCSP 2008; Katsman et al. 2008, 2011). The large uncertainties in the plausible range of LSL trajectories and PDF resulting from these studies greatly reduce the value of these long-term assessments for risk management. A summary of these assessments shows that future LSL variations currently are not predictable on century timescales. Even with respect to the upper end of the range of plausible future LSL trajectories, large uncertainties exist, and recent scientific papers have sent an unclear and mixed message to decision makers and the public (see, e.g., the comments in the New York Times in 2008 and 2009 on recent papers such as Pfeffer et al. 2008; van de Wal et al. 2008; Rignot et al. 2008a; Blanchon et al. 2009; Hu et al. 2009; McPhee et al. 2009).

Following the Fourth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC) (AR4), most of the recent assessments do not assume a significant future contribution from the ice sheets. Recent research has shown that dynamic links between climate and cryosphere are becoming more active (e.g., surface melt influence on ice sheet flow (Zwally et al. 2002), and ice dynamic response to ocean/ice interaction (Motyka et al. 2003; Holland et al. 2008)). Moreover, observed recent changes in the large ice sheets (e.g., Rignot et al. 2008a,b; Jiang et al. 2010; Jacob et al. 2012) as well as glaciers and ice caps (Meier et al. 2007; Pfeffer et al. 2008; Kierulf et al. 2009) indicate that an early onset of significant nonlinear responses of the cryosphere cannot be excluded, thus opening for a significant GSLR already over the next two to three decades. Current ice models cannot provide reliable long-term predictions of such a dynamic response (Lipscomb et al. 2009), and a major uncertainty for global sea-level (GSL) predictions is associated with the contribution from glaciers and ice sheets (see Plag and Jules-Plag 2012 for more details). There is also a potential for rapid GSLR not captured by any of the recent assessments, and the paleorecord may underestimate the maximum possible future rates. Over the past few centuries, humanity has reengineered the Earth in many aspects (e.g., atmospheric composition, land surface use, urbanization, water cycle, and biodiversity) and created states not encountered over the past few million years (see Section 1.03.3 Sea-Level Hazards in Plag and Jules-Plag 2012). The speed of changes in critical Earth system parameters is also unparalleled. Under these conditions, the response of the climate system may also exceed all rapid responses documented in the paleorecords. Thus, unparalleled sea-level change cannot be excluded.

The large uncertainties of any deterministic predictions and the existence of a low-probability, high-impact event (i.e., rapid LSLR) necessitate that risk-based planning considers the extreme event and aims to reduce the potential impact of such an event. The extreme sea-level event is a rapid rise combined with significant increases in storm intensity (area IV in Figure 1). Schwerzmann and Mehlorn (2009) conclude that for most of the countries around the Southern North Sea, climate change would lead to increased storms, and combined with LSLR, to increases in storm surge heights. Even a moderate LSLR limited to 37 cm (corresponding to the IPCC A2 estimate) would lead to an increase of between 36 and 55% in peak surge height compared to present-day levels. For the affected countries, these scenarios require systematic integration of the likely impacts of climate change into risk assessment and risk management processes.

1.03.4 The Assets and Their Vulnerability

As mentioned in the introduction, an increasingly large fraction of the human population is living in the coastal zone, often in urban areas. Air and water qualities have a significant impact on public health, and environmental changes in the coastal zone that negatively impact air and water qualities can have a significant impact on public health in the coastal zone and its hinterland. In many coastal zones, the local population depends on the rich coastal resources such as fishing grounds and mangroves. Healthy socioeconomic conditions are the basis for a healthy population. As discussed by Plag and Jules-Plag (2012), LSLR likely will degrade ecosystem services and thus impact both socioeconomic conditions and public health.

Urban areas host most of the advanced health service infrastructure, such as hospitals and laboratories. In coastal urban areas, this infrastructure is at risk from flooding during storm surges and slow degradations due to long-term effects.

Coastal LSLR can negatively impact health in many direct and indirect ways (Nicholls et al. 2007b; Craig 2010). **Table 1** summarizes the main groups of potential health impacts of LSLR and its associated effects. However, the vulnerability of public health also very much relates to the preparedness and socioeconomic status of communities from villages, towns, and cities to individual nations. For example, Bangladesh experiences only 1% of the world's cyclones but accounts for 50% of the deaths from cyclones worldwide (Khan et al. 2007). A large exposure to sea-level hazards combined with high socioeconomic vulnerability makes the population in the low-lying areas of Bangladesh particularly susceptible to adverse health impacts and threaten development achievements.

A main direct health impact of LSLR is associated with catastrophic flooding caused by storm surges. Coastal flooding has caused many deaths through drowning and other direct causes as well as many injuries. These floods also spread bacteria, viruses, and chemical contaminants. In the aftermath, flooding will foster the growth of fungi and contribute to the breeding of insects.

Flooding can cause environmental conditions leading to increased infectious diseases. Particularly, the spreading of vector-borne diseases, i.e., infections transmitted by the bite of infected arthropod species, such as mosquitoes, ticks, and triatomine bugs, and flies, such as sandflies and blackflies, can be promoted. Both permanent and intermittent flooding will allow vector-borne disease such as cholera and malaria to extend their ranges further inland. More frequent and intense flooding will also increase the number of occurrences and duration of exposure to pathogens. Rodent-borne disease, i.e., diseases carried by rats, mice, squirrels, or other rodents, can also be promoted by flooding because of altered patterns of human–pathogen–rodent contact.

The interruption of health services, energy supplies, communication, and transportation, and the reduced availability of health service staff tends to increase the direct impacts of the flooding. In many urban areas, flooding also results in severe water and air pollution, which will increase infectious and allergic diseases. The impact of Hurricane Katrina on New Orleans in 2005 illustrated the potential direct and indirect health impacts in developed areas of future similar disasters intensified by LSLR (Reible et al. 2006). This case also illustrates the long-term health effects from soil contaminations caused by the heavily polluted floodwaters. The Cyclon Sidr

Table 1 Vulnerability to and impacts of LSLR

Hazard or impact	*Direct health impacts*	*Health infrastructure*
Catastrophic coastal flooding	Deaths through drowning and other causes, injuries, infectious diseases (respiratory, intestinal, skin), mental health disorders	Health services interruption, availability of health staff, transportation disruption, energy and other supplies
Flood-induced pollution	Infectious diseases, allergies	Long-lasting degradation of health service infrastructure
Reduced water quality and reduced access to potable water due to salinification and/or pollution	Diarrheal diseases (giardia, cholera), hepatitis, other water borne diseases	Reduced water supply for health services
Impairment of food quality (through pollution of farmland and fisheries) and reduction of food supply (e.g., loss of farmland and decreasing productivity of fisheries)	Malnutrition; shellfish poisoning, marine bacteria proliferation	Food safety
Change in transmission intensity, distribution of vector-borne disease, abundance of vectors	Changes in malaria and other mosquito-borne infectious diseases	
Population displacements, degradation of livelihoods	Less well defined; can include increased social conflicts; increased crime rate; prostitution to replace lost income	General stress on health services because of rapid changes in demands

Modified from Nicholls, R. J., P. P. Wong, V. R. Burkett, J. O. Codignotto, J. E. Hay, R. F. McLean, S. Ragoonaden, and C. D. Woodroffe, 2007b: Coastal systems and low-lying areas. *Climate Change 2007: Impacts, Adaptation and Vulnerability. Contribution of Working Group II to the Fourth Assessment Report of the Intergovernmental Panel on Climate Change*, M. L. Parry, O. F. Canziani, J. P. Palutikof, P. J. van der Linden, and C. Hanson, Eds., Cambridge University Press, Cambridge, UK, 315–356.

disaster, which hit Bangladesh in November 2007, underlines the multiple health threats resulting from the disruption of water and food supplies, dislocation of people in the areas affected by flooding and the resulting overcrowding in refugee areas, the combination of malnutrition and transmission of communicable disease, vector breeding, and poor access to health services (WHO 2007).

Indirectly, flooding can also lead to pollution of farmland and fisheries, with the consequence of degrading food quality. Polluted farm produce and fish can lead to slow degradation of human health, and increased events of shellfish poisoning can cause a higher death toll. A reduction in food supplies due to a loss of farmland through permanent inundation or erosion could increase malnutrition, particularly in regions of poverty.

The disruption of systems for sanitation, sewage disposal, and storm-water drainage would also have health implications. A reduction in water quality and in the supply of potable water due to pollution will increase the occurrence of cholera and other diarrheal diseases, as well as hepatitis and other water borne diseases. The cholera bacterium has a sea stage, during which copepods (type of zooplankton) act as host organisms (Colwell 2002). Between epidemics, the bacteria can survive with these hosts as an inactive but still infectious sporelike form. LSLR in connection with changes in sea temperature and currents could facilitate the spread of cholera (Colwell 2002), both directly and through contamination of drinking water.

Fish, shellfish, and sea mammals in the marine environment consume algae that are at the base of the marine food web. A reduction in these plankton feeders as a result of overfishing, water pollution, or disease may thus contribute to blooms of harmful algae. Plankton blooms can also harbor cholera and other bacteria, thus increasing health risk.

In combination with higher temperatures in many coastal zones, increased flooding will contribute to resurgence of mosquito-borne diseases, such as malaria, in some areas and the introduction of new mosquito-borne diseases, such as dengue fever, in others (see the reference in Craig 2010). Malaria is already found in areas where it was never found before.

The forced displacement of coastal communities through storm surges or permanent inundation, particularly in areas with limited resources, would further increase the risk of various infectious, psychological, and other diseases.

Although salt water intrusion can have a negative impact on the biodiversity and productivity of estuaries, its effects on public water supply are the most important consequences for public health. The most vulnerable coastal communities often depend on local sources of freshwater. These sources of coastal freshwater can be either surface sources, such as lakes and rivers, or groundwater aquifers accessed through wells. Both sources are vulnerable to salt water intrusion and salinification as a consequence of LSLR.

In coastal aquifers, fresh groundwater normally overlies saline water because freshwater is less dense than salt water. Although the dynamics impacting the interface between fresh and saline waters are complicated and depend on many parameters, a simple static approximation provides a rough estimate expressed by the Ghyben–Herzberg relation (see e.g., Barlow 2003): if h is the height of the groundwater table above sea level and z the depth below sea level of the interface between fresh and saline waters, then

$$z = \frac{\rho_{\mathrm{f}} \cdot h}{\rho_{\mathrm{s}} - \rho_{\mathrm{f}}}, \tag{1}$$

where ρ_{f} is the density of freshwater and ρ_{s} the density of the saline water.

For average freshwater and seawater densities, $z \approx 40h$. Thus, even in areas where the groundwater table is only a few meters above sea level, saline waters are confined to greater depths, and freshwater resources can be extracted for use by humans. Many coastal urban areas depend on water resources in coastal aquifers. However, if freshwater is extracted more rapidly than replenished by rain and inflow from inland aquifers, the groundwater table will fall and the interface between fresh and saline waters will rise. The impact on the interface between fresh and saline waters can be on the order of 40 times the fall in groundwater level. In many cases, water management authorities currently prevent salinification by releasing and recharging freshwater from reservoirs during droughts. Nevertheless, overextraction of groundwater is today the leading cause of salinification of coastal groundwater resources.

However, coastal groundwater resources are also impacted by salinification caused by LSLR (**Figure 2**). As LSL rises, low-lying coastal areas are inundated with saline waters. The height of the groundwater level relative to LSL changes over a wide zone, and this impacts the position of the interface between fresh and saline waters over a large area. This process can lead to a slow salinification of freshwater in wells further away from the inundated area. If not discovered, this slow salinification can have severe direct and indirect impacts on human health. Salinification of coastal aquifers is a long-lasting process. For example, the rapid LSLR of about 120 m at the end of the last glacial period led to salt water intrusions in many aquifers in Florida, where it continues to circulate today (Morrissey et al. 2008).

1.03.5 Risk Assessment

As summarized in Section 1.03.2 Risk-Based Approach to the Impact of Sea-Level Rise on Human Health, the LSLR-related health risk is the product of hazard probability, vulnerability of the assets in terms of health impacts, and the value of the assets exposed. In terms of hazard probability, the authors have outlined that there is a very high probability for a moderate GSLR, resulting in many coastal areas in a high probability for a twenty-first century LSLR on the order of 0.5 m or more. While it is difficult to assess the probability of an extreme LSLR of 2 m or more, such large values cannot be excluded.

Over the past few centuries, the assets exposed in the coastal zones have dramatically increased, and this tendency is likely going to continue. Coastal LSLR has the potential to impact on the order of 50% of all human assets. Vulnerability related to health is high because of several threats, including degradation of health services and infrastructure during flooding, reduced food and water security, increased exposure to disease, and increased pollution of water, air, and soils due to toxic materials and infrastructure inundated by seawater. A main vulnerability threatening public health may, however, not be in

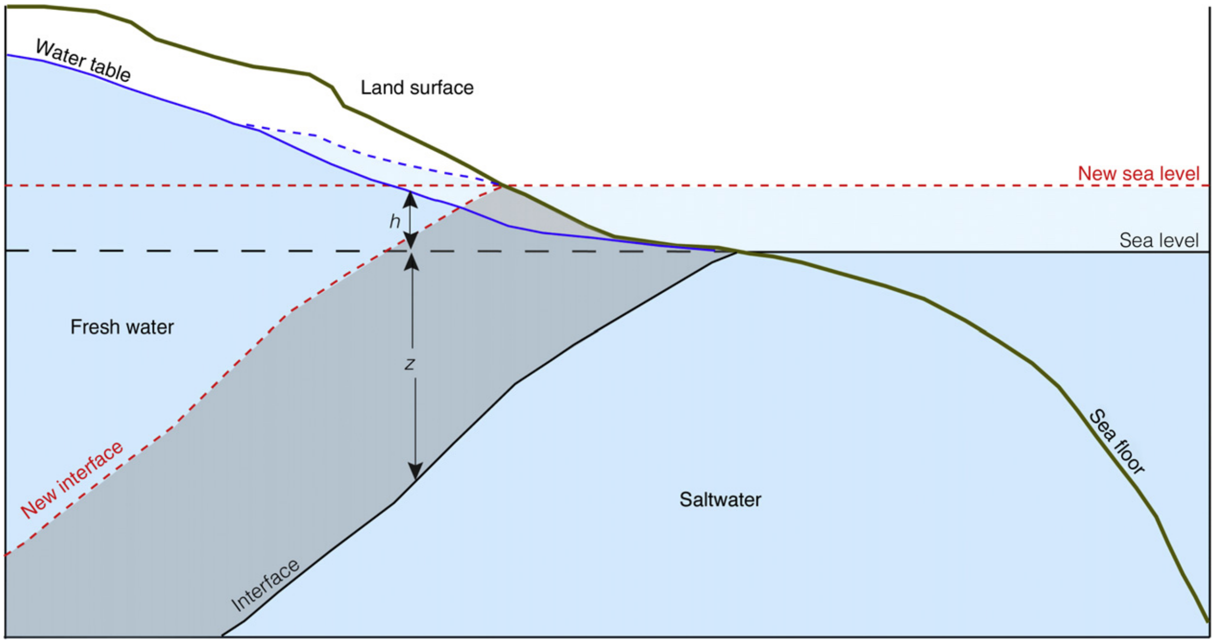

Figure 2 Impact of LSLR on groundwater resources. Depending on the coastal topography, even a small increase in sea level (broken lines) can significantly alter the interface between fresh and saline waters and lead to salinification of groundwater over a wide zone (shaded area). *h* is the height of the water table above sea level, and *z* the depth of the interface between fresh and saline waters below sea level. Modified from Barlow, P. M., 2003: *Ground Water in Fresh Water–Salt Water Environments of the Atlantic Coast, Circular 1262*. U.S. Geological Survey, Reston, Virginia.

the direct and indirect impacts listed here, but rather in the socioeconomic impacts. A significant GSLR and the increased frequency and magnitude of storm surges resulting from the associated LSLR would potentially have devastating impacts on coastal cities and settlements (e.g., Rowley et al. 2007; Edwards 2008), including a 'displacement through flooding and tropical storm activity of up to 332 million people in coastal and low-lying areas' (Watkins and HDR Team 2007). The societal and economic impacts would be felt globally. Loss estimates for single major disasters due to storm surges and hurricanes hitting urban coastal areas in the United States are in excess of $100 billion for the immediate damages (e.g., Chapman et al. 2006; Jacob 2007; Nicholls et al. 2007a). Even the slow increases in GSL projected by the IPCC AR4 (Meehl et al. 2007) would change the risks associated with storm surges and hurricanes in many coastal areas, potentially leading to extreme disasters in coastal areas with dense urban settlements. Regionally, LSLR can exceed the global average rise by 50% and more. A rapid LSLR over a few decades, which cannot be excluded scientifically, would amplify the risks and the ensuing disasters, and it would reduce the time for adaptation.

Consequently, our civilization is challenged by a high health risk associated with LSLR. A detailed quantification of this risk would have to take into account several scenarios for LSLR. For example, if the main source of GSLR would be a rapid melting of parts of the Greenland ice sheet, then the Southern Hemisphere would experience a larger than average LSLR, with severe consequences for the coasts of Africa, South America, Australia, and Southern Asia, while many coastal areas in the Northern Hemisphere would experience lower than average LSLR, and at coastal zones closer to Greenland even an LSL fall. If the main source would be a melting of a part of Antarctica, we would experience the reversed geographical pattern, with a significantly different regional and global risk. If both large ice sheets contribute, the higher latitudes would have lower than average rates, while the lower latitudes would experience the main impact with a larger than average LSLR.

Taking into account the high costs of adaptation and of potential disasters caused by coastal hazards, both over- and underprotection and adaptation can be very costly and can significantly impact national economies. Adaptation may require relocation of settlements (e.g., Vellinga 2007) and major infrastructure, including railroads, highways, and airports (see, e.g., CCSP 2008). Already the projected relatively moderate GSLR puts large numbers of people in vulnerable locations. Complete and partial relocation of populations living in severely affected areas such as Tuvalu, Bangladesh, and Samoa is already creating climate change refugees. Other areas where populations may need to be relocated include the Maldives, Guyana, and the Netherlands. If adaptation, including relocation of people and infrastructure, is delayed and a GSLR as projected or larger happens, large numbers of environmental refugees are likely to result, and inundated infrastructure is likely to cause considerable pollution and environmental impacts. Thus, policy and decision makers are faced with a trade-off between investing today large amounts in coastal protection and adaptation or loading the large human and economic costs of potential disasters on future generations.

Considering the extent of assets at risk in the coastal zone, any significant GSLR will challenge the global society at an unparalleled scale. Therefore, this risk, no matter how low the probability of a GSLR is, cannot be ignored. As pointed out by

Craig (2010), an adaptive management based on a public health approach may be the most suitable approach to address this risk of LSLR.

1.03.6 Conclusions

The risk of a rapid and large LSLR is real for many coastal areas, and even a slow and moderate LSLR has the potential to cause significant changes in storm surge intensity, with severe threats for human health. Reducing the risk associated with LSLR poses two challenges for policy and decision makers trying to formulate adaptation plans: (1) Even a rapid LSLR will seldom exceed a few centimeters per year and will be perceived as slow. Therefore, even in the worst case, realizing climate change-driven LSLR will take decades, and will often be obvious only during storm surges. (2) Predictions of GSLR are highly uncertain, and there is a nonzero probability that the actual GSLR will be outside the projected range of plausible trajectories.

The analysis by Lonsdale et al. (2008) for London shows that extreme scenarios could be highly challenging, even for areas with well-developed institutions. As in the case of London, experts and decision makers are often polarized between two extreme options to reduce the risk: (1) reconfiguring the urban area around the rising sea and (2) building new barriers that would allow the urban areas to continue as today. In many coastal areas, this lack of consensus has the potential for paralysis in response to the low-probability, high-impact extreme LSLR. In the case of rapid LSLR, it could lead to an unplanned response as the existing defense capabilities are overwhelmed. Hence, any extreme, low-probability, high-impact LSLR will likely challenge the existing institutions. Adaptive management is presented by Lonsdale et al. (2008) as an approach to address this challenge. Adaptive management has the ability to react to new information concerning the magnitude and speed of LSLR as that information becomes available. It also helps decision makers not to be overwhelmed by the scientific uncertainties about the trajectory of future LSLs (Craig 2010).

Adaptive management addresses core concerns, which will lead to improvements no matter how LSL is going to change, and at the same time will reduce the risk of disasters if LSL rises significantly. The core concerns for coastal areas identified in the previous sections relate to (1) the availability of potable water; (2) the potential for toxic contamination of water, air, and soil as seawater inundates coastal areas; and (3) potential changes in the exposure to diseases. The first requires drinking water supplies based on resources less prone to salinification, and to reduce other pollution threats for these resources. The second may necessitate changes in land use in the coastal zone and the removal of toxic material and infrastructure from potential inundation areas in the coastal zone. The third might lead to changes in health services and training needs. In each of these areas of core concerns, governments and planners can identify adaptation measures that can be implemented immediately, which will increase resilience and be beneficial to coastal communities independent of the actual impacts of LSLR on these communities.

In the absence of actionable century-scale GSL and LSL predictions, recently, several city managers have indicated that 'early warnings' for a rapid LSL rise with lead times of 5–15 years would provide actionable information for decision makers (e.g., T. Reeder 2009, personal communication). Such short lead times require a continuously operating LSL forecasting on decadal timescales (e.g., Plag et al. 2010). To a certain extent, such a service would be comparable to the ongoing sky watch for near-Earth objects, which aims to provide early detection of the low-probability/high-risk event of a large object approaching Earth. The development of policies and mitigation and adaptation strategies for resilient coastal areas would benefit from an LSL service that combines continuous observations of key components of the Earth system (such as the ice sheets, ice caps, and major glaciers; ocean currents; ocean temperature; land water storage; sea surface height changes; and vertical land motion) with models that assimilate these observations and forecast short-term (years) and intermediate (decades) LSL changes. Such a service is required in order to facilitate adaptive management where and when necessary. Of particular importance is the continuous monitoring of the large ice masses in order to identify any ice masses that enter a state of instability. For these masses, predictions of their disintegration trajectories will be possible. On the basis of such disintegration predictions, LSL can be forecast with the same time horizon as for the ice sheets if a validated ice–ocean–solid-Earth model is available. Likewise, ocean observations will be able to detect the onset of major changes in ocean circulation and heat content affecting GSL and LSL, and validated atmosphere–ocean models will be able to forecast further development on decadal timescales. Living on a reengineered planet with potentially unprecedented rapid changes requires a well-developed monitoring and predictive system to inform decision makers in a timely manner about any pending extreme events.

Glossary

Desertification land degradation caused by climate and human activities.

Drought a temporary lack of water caused primarily by climate, which negatively affects the environment and human society.

Environmental change the biophysical transformation of land, water, and the atmosphere as a result of both natural processes and human activities.

Ecosystem services the benefits from ecosystems that enable humans to survive and that support their quality of life.

Human well-being a multidimensional concept encompassing all aspects of human experiences including the environment, health, education, social relations, livelihood opportunities, security politics, and governance.

NDVI Normalized Difference Vegetation Index derived from satellite-borne instruments is a numerical indicator of vegetation greenness, which can be compared across different images.

1.04.1 Introduction

Environmental change describes the biophysical transformation of land, water, and atmosphere as a result of both natural processes and human activities (von Falkenhayn et al. 2011). It occurs at a range of scales from local to global and affects the social and economic well-being of human society, primarily through its impact on ecosystem service provision. Such services can be described as the benefits from ecosystems that enable humans to survive and that support their quality of life (Harrington et al. 2010) (Table 1). They include provisioning services such as food and water, regulating services derived from the interaction of biotic and abiotic elements, cultural services, and supporting services such as primary production and nutrient cycling (MA 2005). Although pathways are incompletely understood, ecosystem services are strongly linked to human well-being (Butler et al. 2005) through their general influence on people's safety and

http://dx.doi.org/10.1016/B978-0-12-384703-4.00106-4

Table 1 The main ecosystem services (with selected examples) provided by the environment for human society as well as the human well-being criteria necessary for a good quality of life, based on the conceptual framework and terminology developed by the Millennium Ecosystem Assessment (MA 2005)

Ecosystem services	*Human well-being*
Provisioning (food, water, fuel wood)	Security (personal safety, secure resource access, security from disasters)
Regulating (climate, water)	Basic material for good life (food, shelter, adequate livelihood)
Cultural (spiritual, recreational)	Health (strength, feeling well, access to clean water)
Supporting (primary production, nutrient cycling)	Good social relations (social cohesion, mutual respect)
	Freedom of choice and action (opportunity to be able to achieve what an individual values doing and being)

MA, 2005: Ecosystems and human well-being: current state and trends. Hassan, R., R. Scholes, and N. Ash, Eds., Findings of the Condition and Trends Working Group, [Available online at http://www.millenniumassessment.org/en/index.aspx.]

access to basic resources, including food and shelter, which in turn affects people's health and the societies in which they live. Ultimately human well-being is determined by the choices that people make and their opportunities in life.

We focus initially on the impact of direct drivers on African environments (Figure 1). These include natural processes such as climate and drought, as well as those resulting from human activities such as land use, land cover change, and invasive species introductions. The authors first describe the extent, nature, and rate of change that has occurred in African environments in response to each of these pressures with an emphasis on the Sahel, eastern and southern African regions. The role of indirect drivers such as society and politics or demographic shifts, which are often influenced by policy or management decisions, or individual responses such as mobility and migration, are also discussed in terms of their impact on environmental states. Next, how these changes have affected ecosystem service provision and human well-being is discussed. Although indirect drivers and people's responses clearly impact strongly on human well-being, a thorough discussion of these interactions is beyond the scope of this review. Finally, the authors document historical trajectories and explore some of the counter narratives of environmental change and its potential impact in Africa.

This contribution adds to the rapid recent awareness of the full role that humans have played in global environmental change. It draws on the work of the International Human Dimensions Programme on Global Environmental Change (Von Falkenhayn et al. 2011) as well as the Millennium Ecosystem Assessment initiative (MA 2005). The comprehensive synthesis undertaken by Scholes and Biggs (2004) for sub-Saharan Africa has particular relevance, in addition to UNEP's Africa Environment Outlook (UNEP 2006) and their Encyclopedia of Earth initiative (www.eoearth.org).

1.04.2 Environmental and Social Circumstances in Africa

Africa straddles the hemispheres, is more than 8000 km long and 7500 km wide, and covers about 30 million km^2 or one-fifth of the world's total land area. The continent possesses high seasonal, annual, and decadal variability in its climate, which is influenced by a number of large-scale, intra- and interhemispheric climatic processes and weather systems. These include the circumpolar westerlies, the West African Monsoon, the Intertropical Convergence Zone (ITCZ), and the El Niño–Southern Oscillation. Sea surface temperatures (SSTs) appear to have a particularly important influence on decadal scale variability in Africa's climate (Mohino et al. 2011).

The continent is dominated by woodlands, shrublands, and grasslands, which comprise 42% of Africa's land surface (Mayaux et al. 2004) (Figure 2; Table 2). Agriculture occurs on about 12% of the continent, while a third of Africa's land surface is comprised of bare soil. Although anthropogenic impacts such as herbivory and fire do have an important influence on vegetation type and cover at local scales (Bond 2008), natural environmental factors, particularly annual precipitation (Figure 3), are excellent predictors of the distribution of vegetation in Africa, especially that of forest and bare soil cover (Greve et al. 2011).

In 2010, about 1 billion people, or 15% of the world's population, lived in Africa. Between 2005 and 2010, Africa's population grew at 2.3% and is expected to rise to between 1.93 and 2.47 billion people by 2050, contributing more than half of the increase expected in the world's population. Africa's high infant mortality rate of 96 deaths in 1000 and relatively low life expectancy of 55.2 years are the worst human health indicators of any continent (United Nations 2011).

Africa's annual per capita gross domestic product (GDP) in 2009 was US$2005 (United Nations 2011), or about 7% of that of countries with high human development. Overall, 78% of the continent's population lives on less than US$2 a day (UNEP 2010) and 330 million sub-Saharan Africans live in extreme poverty (Hellmuth et al. 2007). Such statistics hide the considerable variation in poverty levels between different regions and countries and also between people living in urban and rural settings. With a current rate of urbanization of 3.5%, more than 53% of Africa's population is expected to live in urban areas by 2030 (UNEP 2010).

The economies of many African countries are strongly reliant on their agricultural base, (UNECA 2008) and the amount of rain, or lack thereof, can have a significant influence on the national GDP (Hellmuth et al. 2007). While over 56% of Africa's labor force is employed within the agricultural sector, more than 90% of rural Africans are engaged in some form of agricultural activity (UNEP 2010). Although agricultural production has declined in recent years, it represented 20–30% of sub-Saharan Africa's GDP and 55% of its exports at the end of the twentieth century (Elasha et al. 2006). Despite the high level of involvement of Africa's population in agricultural activities, the continent spends up to US$20 000 million each

year on food imports, in addition to the US$2000 million it receives annually in food aid (UNEP 2010). Approximately half the World Food Aid Programme's annual budget is spent on food aid to the continent (UNECA 2008). Even so, the Food and Agricultural Organisation estimated that in 2009, 265 million people in sub-Saharan Africa were suffering from chronic hunger, while undernutrition causes 1.7 million deaths in Africa every year (Ramin and McMichael 2009).

1.04.3 The Impact of Drought in Africa

1.04.3.1 Climate Variability Over Longer Timescales

Paleoclimatic reconstructions of Quaternary environments for northern Africa indicate that glacial periods have generally been arid, while the interglacials have been more humid (Brooks 2004). There is considerable variability, however, on millennial and centennial timescales. For example, the first half of the Holocene, from about 9000 to 4000 years BP was significantly wetter than at present (Lézine et al. 2011), and the region contained a series of interlinked waterways formed by a large interconnected series of rivers, lakes, and inland deltas (Drake et al. 2011). During this period, known as the African Human Period (deMenocal et al. 2000), significantly more areas of the Sahara Desert were dominated by semiarid tropical savanna vegetation than at present (Watrin et al. 2009). This early Holocene humid phase facilitated the dispersal of humans across northern Africa into areas that are uninhabitable today (Drake et al. 2011). Whether rapid and nonlinear (Brooks 2004) or gradual and progressive (Kropelin et al. 2008), a spatially variable aridification phase started about 5500 years BP (Lézine et al. 2011). This resulted in a decrease in vegetation cover and a contraction of species associated with more humid environments leading to the present-day desertlike conditions, which were already established around 2700 years BP (Kropelin et al. 2008). The last millennium was characterized by repeated wetter and drier phases, sometimes of greater magnitude than anything experienced in the region in the last 100 years (Shanahan et al. 2009).

Environmental indicators and proxy measures derived from endoreic lake levels, pollen cores, and fluvial sediments suggest that eastern Africa has experienced cycles of aridity, degradation, and stability during the Holocene (Marshall et al. 2011). As for northern Africa, Nyssen et al. (2004) describe a cold and dry late Pleistocene (20 000–12 000 years BP), a wetter early Holocene (11 500–4800 BP), and then a shift to more arid as well as more erosive conditions after this period. Although there is temporal and spatial variability, a general warming trend over the last 350 years is evident for eastern Africa (Kiage and Liu 2009; Thompson et al. 2009). Extreme drought conditions have also been documented for western Uganda and central Kenya about 200 years ago as a result of a subcontinental scale reduction in rainfall at this time (Bessems et al. 2008).

Southern Africa appears to have experienced periods of rapid warming and cooling during the Holocene, which are generally in phase with those for northern and eastern Africa (Scott et al. 2008; Chase et al. 2010). For example, in Namibia, evidence from fossil hyrax middens suggests fluctuating phases of relatively humid conditions from 8700 to 3500 years BP after which a period of marked aridity developed, lasting until 300 years BP (Chase et al. 2009). While centennial and

millennial-scale suborbital events and variations in solar activity appear responsible for some of the fluctuations in southern African climate, these patterns are most strongly correlated with the relatively predictable change in high-latitude, Northern Hemisphere summer insolation cycles driven primarily by orbital precession (Chase et al. 2009, 2010). It is within these long-term changes in African climates that events of the twentieth century should be interpreted.

1.04.3.2 The Incidence of Drought in Africa in the Twentieth Century

1.04.3.2.1 Spatial Variability of Drought in Africa

Droughts can be conceived of as a temporary lack of water caused primarily by climate, which negatively affects the environment and human society (Kallis 2008). Because Africa comprises extensive arid and semiarid areas with unpredictable rainfall, the incidence of drought is high (UNECA 2008; Dai 2011a). It has had a devastating impact on African environments and societies for millennia (Touchan et al. 2011), particularly in the Sahel and Greater Horn of Africa (GHA) regions. Relative to the wide-scale loss of life and social disruption that accompanied the Sahelian droughts of 1968–74 (Batterbury and Warren 2001) or the most recent 2010–2011 drought in the GHA region (Loewenberg 2011), the impact of drought in southern Africa in the twentieth century has been largely agricultural and economic, rather than social and life-threatening (Benson and Clay 1998; UNECA 2008).

1.04.3.2.2 Case Study: The 1968–1974 Drought in The Sahel

Environmental Collapse in the Sahel

The Sahel stretches over 5000 km across the width of Africa roughly between 10 and 20°N in a broad transition zone between the arid Sahara desert in the north and the more mesic

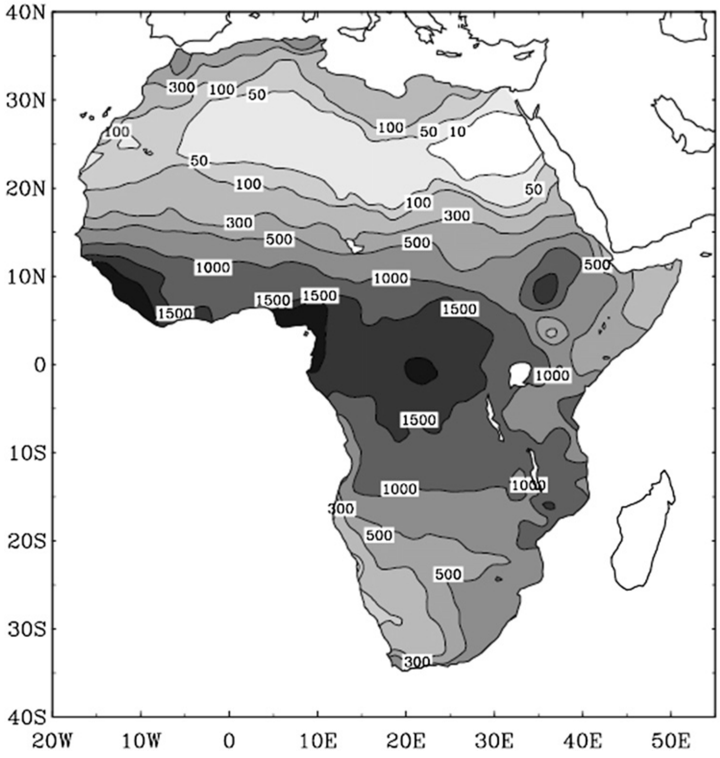

Figure 3 Mean annual rainfall (in millimeters) for Africa. From Nicholson, S., 2001: Climatic and environmental change in Africa during the last two centuries. *Clim. Change*, **17**, 123–144.

savanna environments in the south. The 200- and 600-mm rainfall isohyets provide the conventional climate bounds of the region (Hein et al. 2011). Because of its geographic position and relatively high population densities, the Sahel is vulnerable to both climate and land-use impacts (Hein 2006). In addition to the high interannual variability in rainfall, the region is also characterized by spatially coherent, decadal scale fluctuations in rainfall amounts (Caminade and Terray 2010). The first part of the twentieth century and particularly the 1950s were relatively wet, while a series of devastating droughts were experienced in the region from the late 1960s to the early 1990s (Nicholson 1993) (**Figure 4**). The extent and severity of this sustained 20–30% decline in rainfall was unprecedented in the observational record not just for the Sahel but also for anywhere on Earth (Hulme et al. 2001).

These droughts had a significant effect on the vegetation of the region. In an extensive 11-month field study in 1993–1994 undertaken along a 1900-km transect in Senegal in the western Sahel, Gonzalez (2001) documented the long-term changes in forest vegetation of the Sahel, Sudan, and Guinean vegetation zones in response to the extended Sahelian droughts of the 1970s and 1980s. He used a combination of field surveys, participatory mapping, and aerial photograph analysis and showed that from 1945 to 1993, the Guinea and Sudan vegetation zones had contracted southwest at an average rate of 500–600 m year^{-1} (**Figure 5**). Average species richness within areas of 4 km^2 declined by about a third from 64 to 43 species with the more mesic Guinean tree and shrub species most affected. From the aerial photographic analysis, he documented a 22% decrease (from 10 to 7.8 trees per hectare) in the density of trees >3 m in height. Traditional firewood species had also declined as had useful medicinal plants and those species that provided fruits, leaves, and gum during drought emergencies. He concluded that the region had 'lost its capacity' to support current population densities and would be unable to do so under future drought conditions.

Climatic Determinants of Sahelian Drought

Gonzalez (2001) showed that changes in rainfall and temperature over the study period best explained the changes in tree richness, density, and distribution and that a change in SST appeared partially responsible for the reduction in rainfall. Subsequent research has shown that variability in twentieth century Sahelian precipitation is strongly influenced by SST in the Atlantic and Indian Oceans (Giannini et al. 2003; Huber and Fensholt 2011; Williams and Funk 2011; Wolff et al. 2011) as well as teleconnections involving the El Niño–Southern Oscillation (ENSO) phenomenon in the Pacific Ocean (Caminade and Terray 2010). Using a general circulation model (GCM) Mohino et al. (2011) explored the relative contribution of these potentially competing atmospheric components to the variability in twentieth century Sahelian precipitation. They found that decadal, multidecadal and long-term trends in SSTs in the Atlantic, Indian, and Pacific Oceans explained most of the variability in rainfall. For example, 50% of the droughts in the 1980s could be explained by the Atlantic Multidecadal Oscillation (AMO), 40% by the interdecadal Pacific Oscillation (IPO), and 10% by the long-term global warming trend in the tropical Indo-Pacific and Tropical Atlantic Oceans. Mohino et al. (2011) provide mechanistic explanations for these impacts including patterns of subsidence and shifts of the ITCZ in response to different atmospheric influences. They also partition the contribution of each component to the mid-1990s partial recovery in rainfall in the Sahel (**Figure 4**), which they suggest was largely driven (80%) by the AMO.

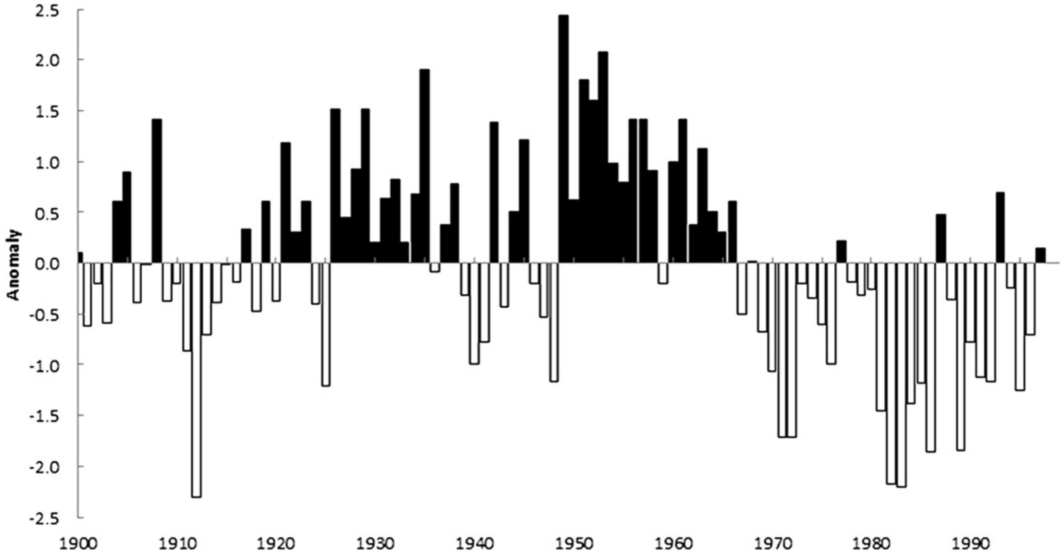

Figure 4 Anomalies (+SD) relative to the long-term mean in spatially aggregated annual rainfall for the Sahelian zone for the period 1901–98. Anthropogenic Determinants of Sahelian Drought

Gonzalez (2001) and others (e.g., Sinclair and Fryxell 1985; Miehe et al. 2010) have also highlighted the potential influence that anthropogenic impacts could have had on regional weather patterns as a result of large-scale transformation of the Sahel's vegetation cover and the associated effect that this might have on the hydrological cycle and land–atmospheric processes (Los et al. 2006). However, many remote-sensing studies suggest that land-use impacts are not immediately evident at large spatial scales. For example, Seaquist et al. (2009) used the National Oceanic and Atmospheric Administration's (NOAA) advanced very high resolution radiometer (AVHRR) Normalized Difference Vegetation Index (NDVI) for the period 1982–2002 and compared composite NDVI values with modeled values predicted by the Lund Potsdam Jena-Dynamic Global Vegetation Model (LPJ-DGVM) for the same period. Differences in the output for each cell were then related to a land use and population pressure data set and assessed in terms of the potential impact of people on vegetation greenness. Like Hickler et al. (2005), Herrmann et al. (2005), and Fensholt and Rasmussen (2011), their results provided no evidence that livestock production has significantly affected the broad-scale vegetation dynamics of the region over the period of study, although pasture production might have positively influenced NDVI scores. However, the effects of negative local-level impacts on vegetation greenness, which are not detectable by satellites, are emphasized. Hein et al. (2011) suggest more generally that further work is necessary to determine the anthropogenic effects of land use on Sahelian environments as measured from satellite-borne instruments. They caution against accepting too uncritically the view that twentieth century land-use practices have not had a significant negative effect on Sahelian environments (Hellden 1988). Land degradation clearly occurs as a result of a multiplicity of factors, and it is often difficult to isolate individual causative factors such as a particular land-use practice (Mbow et al. 2008).

1.04.3.3 The Impact of Drought in Africa

1.04.3.3.1 Drought Impact in the Sahel

The widespread and extensive drought between 1968 and 1974, in particular, led to an unprecedented environmental emergency and humanitarian crisis in the region and severe economic hardship for the people of the Sahel (Berg 1976; UNECA 2008). It was a major 'historical marker' (Batterbury and Warren 2001) and propelled the issue of land degradation onto the world stage, beginning a number of global initiatives such as the World Meteorological Organisation (WMO) expert missions in the region in 1972 (Sivakumar et al. 2011) and the United Nations Conference on Desertification (UNCOD) in 1977 (Herrmann et al. 2005).

While several statements exist of the 'hundreds of thousands of people' who died and the 'millions of animals' (UNEP 2004; UNECA 2008) that perished in the 1968–1974 Sahel drought, surprisingly few analyses of the impact of this drought on human well-being have been published. The most important is probably that of Berg (1976) whose findings focused both on the 'irreversible' effects of the drought, such as loss of life, extended periods of malnutrition, and environmental transformation, as well as on the 'reversible' effects such as the decline in agricultural output and the balance of payments. Malnutrition and hunger were certainly widespread as evidenced by the fact that in 1974, as many as 750 000 people were directly dependent on food aid (UNEP 2004). Data for cattle losses suggests that as many as a third of the animals perished in the drought. In Senegal, average output for the production of groundnuts and cotton, the country's main cash crops, fell by 25% relative to average values for the mid-1960s. In countries such as Chad, Mali, and Niger, the production of cereal crops such as millet and sorghum was similarly affected and fell by about a third in 1973–1974 relative to the mid-1960s (Berg 1976). Overall reduction in agricultural output for some of the worst affected countries such as Chad, Mali, Niger, and Senegal was between 12 and 21%. For people who were already very poor, such impacts reflected an extraordinarily severe loss (Berg 1976).

1.04.3.3.2 Drought Impact in Eastern and Southern Africa

The impact of drought in other parts of sub-Saharan Africa have also been documented including the 1983–1984 Ethiopian famine in which a million people are estimated to have died (Hellmuth et al. 2007) and the 2003 and 2005 droughts in eastern and southern Africa, which threatened the lives of 14 million people (UNECA 2008). On the basis of several studies undertaken at this time, Ramin and McMichael (2009) documented what it meant for a child's nutritional and growth status if born in a drought year. For example, early twenty-first century droughts increased the likelihood of a child being undernourished by 36% in Ethiopia and 50% in Kenya. Such children were also more likely to be stunted relative to their peers (by as much as 2.3 cm) with significant long-term impacts on a range of human well-being indicators including lifetime earnings. The impact of drought was also greatest in poorer households and further exacerbated income inequality particularly within the rural economy, probably because it is usually accompanied by the loss of income and the widespread sale of assets (Benson and Clay 1998).

Ifejika Speranza (2010) carried out a detailed, longitudinal study on the impact of climate variability and drought on 127 agropastoral households located in a semiarid transition zone in southeastern Kenya. In these marginal environments, which receive less than 800 mm per annum, agropastoralism, nomadic pastoralism, and conservation are the major land-use practices. Since 1980, the region has experienced seven major droughts with the 1999–2000 drought resulting in the loss of 52% of the livestock kept by households. Nonclimatic factors, including the failure of livestock and food markets; local conflicts over resources; and an increase in livestock theft also contributed significantly to the impact of drought on people and the environment.

The severe economic impact of the 1991–1992 drought in South Africa provides some measure of the extent to which even relatively complex economies are affected by drought. Pretorius and Smal (1992) suggested that this particular drought resulted in a 27% decline in agricultural GDP, which directly accounted for a 1.5% fall in overall GDP and the further spending of over US$600 million on maize imports in 1992 alone and which continued to 1995. Over the same period, 49 000 agricultural sector jobs and 20 000 formal, nonagricultural sector jobs were lost (Benson and Clay 1998).

1.04.3.3.3 Impact of the 2010–11 Drought Crisis in the GHA

Since the last quarter of 2010, severe drought in the GHA has resulted in widespread famine, loss of human life, loss of livestock, and mass migration. While it is still too early to assess the full impact of this disaster, first reports indicate that the lives of about 12 million people in the region have been affected, a third of whom are from war-torn Somalia (Loewenberg 2011). As many as 3.7 million people are food insecure, with more than 390 000 children considered acutely malnourished. The drought has led to widespread migration, particularly in southern Somalia, and some refugee camps in neighboring countries such as in northern Kenya have received an average of 1300 people a day. Overcrowding and unsanitary conditions have led to widespread outbreaks of life-threatening diseases such as diarrhea and measles. Acute malnutrition affects nearly a third of the refugees in some camps, with conditions on the outskirts of these camps even more dire. High poverty levels and the inability of people to afford the 300% rise in the price of local grains have exacerbated the problem as has conflict and war in the region. Loewenberg's (2011) editorial provides a distressing account of the scale and impact of the tragedy in the GHA, which has experienced its worst drought in 60 years. It also highlights the confounding effect that nonclimatic factors, such as civil conflict and food prices have on the well-being of people living under such conditions.

1.04.4 Land Use and Land Cover Change

1.04.4.1 Agriculture, Ecosystem Productivity, and Soil Erosion

Although estimates vary, about 12% of Africa's land surface is used for agriculture, by far the majority of which is rain fed (Mayaux et al. 2004) (Table 2). While the act of tilling the soil provides food for Africa's growing population, inappropriate cultivation practices can also have devastating consequences for both on- and off-site environments primarily through soil loss, reduction in soil fertility, and ecosystem productivity. Recent satellite-derived estimates of soil erosion in sub-Saharan Africa show that it is most serious in the humid subtropics and tropical savannas, as well as in some of the semiarid areas in the southwest (Symeonakis and Drake 2010) (Figure 6). High rates of erosion are related to slope steepness, soil erodibility, rainfall, and the impact of land use.

1.04.4.1.1 Eastern Africa

Within the northern Highlands of Ethiopia, satellite-derived indices of land degradation suggest that despite the widespread introduction and success of soil water conservation (SWC) measures in the region (Frankl et al. 2011), ecosystem productivity has declined in the past 10 years over large areas (Rowhani et al. 2011). Gebresamuel et al. (2010), for example, describe the negative effects of land-use change between 1964 and 2006 in two catchments from the highlands of Tigray. Both areas showed a substantial increase in settlement area and cultivated land and a decrease in forest and woodland over

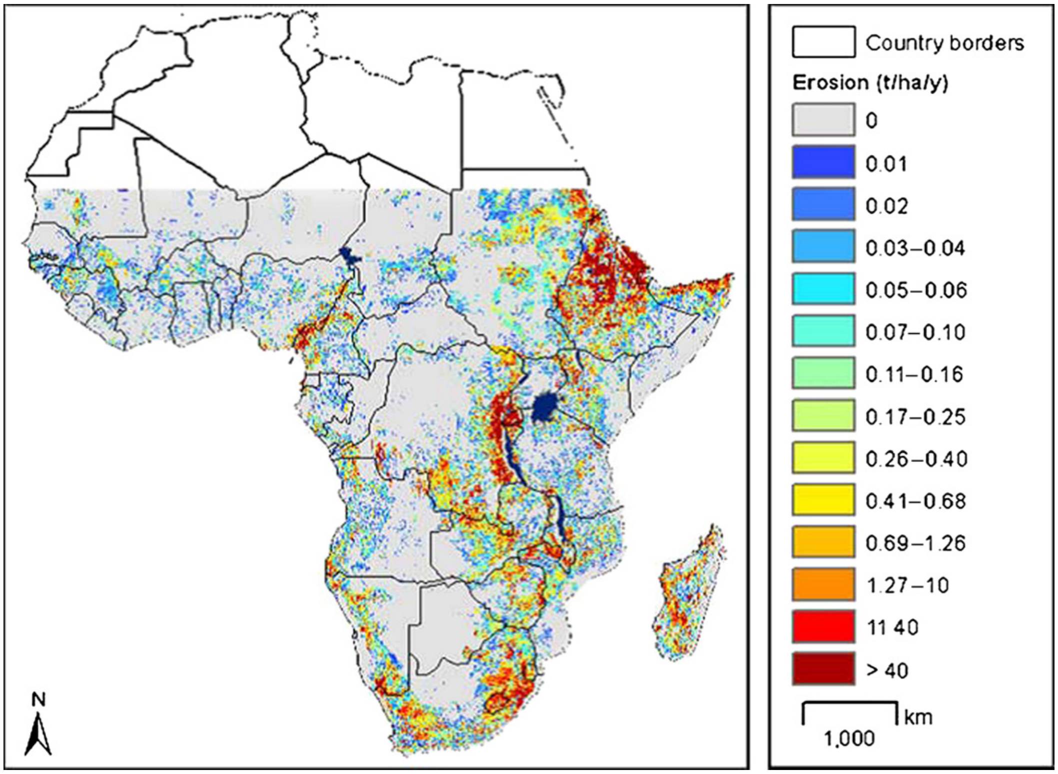

Figure 6 Satellite-derived estimates of the extent of soil erosion (tonnes per hectare per year) in sub-Saharan Africa. From Symeonakis, E., and N. Drake, 2010: 10-Daily soil erosion modelling over sub-Saharan Africa. *Environ. Monit. Assess.*, **161,** 369–387.

time. Surface runoff increased and soil water storage capacity decreased in both catchments in response to the changes in land use and land cover over this period. In southern Ethiopia, Moges and Holden (2008) describe a rapid down-slope development of gullies over the past 30 years, with average soil loss rates of 11–30 $\mathrm{t\,ha^{-1}\,year^{-1}}$, which they suggest are unsustainable in terms of the agricultural production levels required in the future.

Using the 1981–2003 NOAA-AVHRR NDVI time series, Bai and Dent (2006) assessed the extent of environmental change in Kenya. Net primary production (NPP) decreased in 20% of Kenya primarily within marginal cropping environments. In UNEP's Atlas of Kenya's changing environment (2009), the subdivision of marginal land into uneconomic production units, as well as the influx of large numbers of people into increasingly marginal arid and semiarid areas, is blamed for the increase in the extent of degraded land, which is thought to affect nearly 12 million people.

Rohde and Hilhorst's (2001) analysis of 26 repeat photographs from the Lake Manyara area in northern Tanzania provide evidence of dramatic change and, in some instances, severe land degradation associated with cultivation. The most extensive degradation was recorded in the more marginal environments of the Ardai and Makuyuni Plains, which are characterized by low and variable rainfall. Here, extensive cultivation and subsequent abandonment of old lands has resulted in widespread gully erosion and increased runoff from cultivated fields particularly during extreme rainfall events.

1.04.4.1.2 Southern Africa

The 0.9 million $\mathrm{km^2}$ Orange River catchment is the largest in southern Africa and the most turbid in Africa (Compton et al. 2010). Using estimates of mean mud flux derived from marine cores on the western margin of South Africa that span the last 11 500 years, Compton et al. (2010) have suggested that land-use practices associated with settled agriculture in the catchment could have resulted in a sediment discharge as high as 60 million metric tons/year. The mud flux value associated with such a discharge rate is 10 times greater than average values for the Holocene. This, in turn, translates to a 100-fold increase in total soil erosion compared to values for the catchment before settled agriculture.

A national review of land degradation in South Africa (Hoffman and Ashwell 2001) suggested that soil erosion was influenced by both biophysical and socioeconomic factors. Land tenure as well as poverty indices, for example, were both significant predictors of the extent and severity of land degradation in a district as were slope steepness and soil erodibility (Hoffman and Todd 2000). Communally managed areas have consistently returned greater rates of land degradation in Southern Africa (McCann 1999), although there is considerable variability between areas (Wessels et al. 2007). The most important impacts of soil erosion include a decline in crop yield and greater susceptibility to drought; an increase in the rate of dam, reservoir, and estuary siltation (Boardman and Foster 2011); and, in severe cases, the loss of arable land (Garland et al. 1999).

1.04.4.2 Pastoralism and Rangeland Degradation

The livestock production sector is an important activity and source of income for more than 200 million Africans across the continent. It is carried out under a wide range of tenure arrangements and production systems including industrial, agropastoral and pastoral, and smallholder crop-livestock systems (Thornton et al. 2006). Livestock are important assets for any household and help to diversify risk and improve resilience to unexpected shocks such as drought. Livestock also provide a range of spiritual, religious, and economic services for their owners in addition to meat, milk, draught power, and transport. Vulnerability to livestock loss or production failure is influenced by several factors including drought, theft, and land degradation.

Land degradation and the impact of livestock on the composition of African rangelands and their continued ability to provide the necessary services has been the subject of considerable debate over the past two decades (Vetter 2005) and has important implications for how rangelands have been managed (Rohde et al. 2006). While the 'new thinking' in rangeland ecology (Ellis and Swift 1988; Behnke et al. 1993) challenged received wisdom concerning the nature, extent, and causes of land degradation, individual case studies as well as experimental quantification (Du Toit et al. 2009) continue to highlight the impact of persistent high stock numbers on the structure and function of African rangelands. For example, in both the southeastern (Abate et al. 2010) and southwestern (Gil-Romera et al. 2011) parts of Ethiopia, where pastoralism and agropastoralism are the dominant land-use practices, the long-term impact of high human and livestock densities has resulted in significant encroachment by woody plants onto previously productive grassland environments. Most herders themselves consider their rangelands to be in a 'poor condition' (Abate et al. 2010), with important implications for the livelihoods of user communities. For example, ongoing drought conditions together with the extensive degradation of rangeland resources have increased poverty levels in the eastern parts of Ethiopia and have also affected herd composition with camels and small ruminants replacing cattle (Kassahun et al. 2008).

In South Africa, where livestock mobility is severely constrained by overcrowding and the historical legacies of apartheid planning, heavy stocking rates have transformed significant parts of the country. This is particularly visible in the communal areas where stocking rates are on average 1.85 times greater than neighboring private leasehold farms (Hoffman and Ashwell 2001). In the communal areas of semiarid Namaqualand, in the western part of South Africa, heavy grazing has resulted in the reduction of palatable perennial plants and an increase in annual and geophytic species (Anderson and Hoffman 2007). However, the impact appears spatially heterogeneous with lowland environments affected to a far greater degree than rocky upland environments (Anderson and Hoffman 2011). The transformation from a perennial shrubland to an annual, herb-dominated flora renders such transformed ecosystems vulnerable to the impact of drought since, when rains fail, very little forage is available for livestock. In contrast, within perennial shrub-dominated landscapes, the potential at least exists for the interannual transfer of forage production, which buffers the fluctuations in livestock production to some extent (Todd and Hoffman 2009). However, despite the impact that heavy grazing has had on both plant composition and soil fertility in the region, Benjaminsen et al. (2006) have shown that very high livestock numbers can be maintained over decades in the communal areas even though they fluctuate significantly in response to drought and good rainfall conditions.

1.04.4.3 Bush Encroachment

Bush encroachment is the increase in cover, density, and biomass of indigenous woody trees and tall shrubs (van Auken 2009). It has transformed the structure and function of many savanna and grassland environments across Africa, with important consequences for ecosystem services and agricultural-based livelihoods (Kassahun et al. 2008) (Figure 7). While some consider it a cyclical phenomenon (Wiegand et al. 2006; Gil-Romera et al. 2010), others consider it a progressive process and a problem primarily of the twentieth century (Rohde and Hoffman 2012). In some instances, it also reflects a return to the kind of landscape that existed prior to it being cleared for cultivation (Puttick et al. 2011). While estimates of the extent of bush encroachment for the continent are lacking,

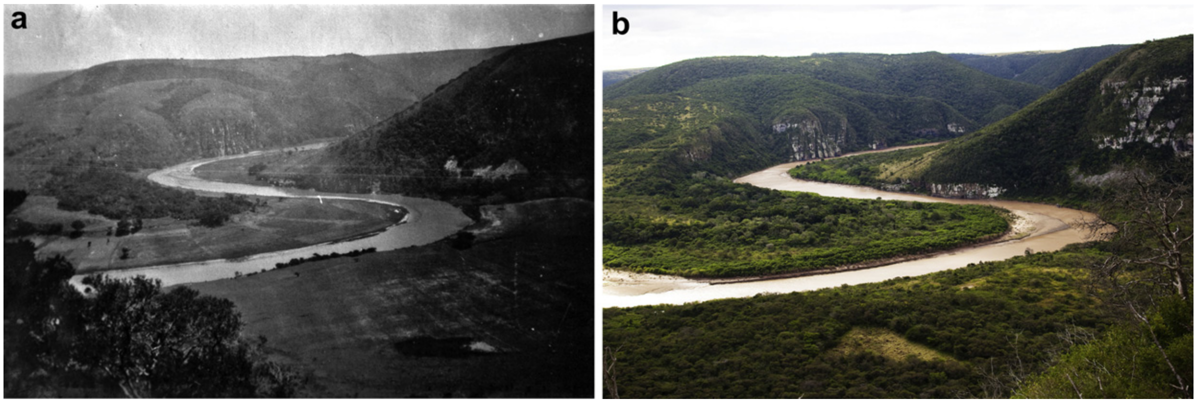

Figure 7 Change in woody plant cover on abandoned cultivated fields and on slopes and ridgelines near the mouth of the Kei River, South Africa between *c.* 1920 (left) and 2011. Unpublished photograph reproduced with permission from James Puttick.

in some countries, such as Namibia, as much as 12 million ha are heavily encroached upon by 'problem bushes' (De Klerk 2004).

Depending on prevailing rainfall conditions and disturbance regimes (Bucini and Hanan 2007), increases in tree cover can be rapid. Munyati et al. (2011), for example, recorded a 50% increase in bush-encroached areas at a mesic South African savanna site in as little as 6 years, while in another mesic South African savanna, woody plant density increased by 194% over three decades (Buitenwerf et al. 2011). Woody plant increase is far less of an issue in arid savannas. For example, in Namibia, areas below a mean annual rainfall of 275 mm have not exhibited an increase in woody plant cover over more than 130 years (Rohde and Hoffman 2012).

Several reasons for the increase in tree cover have been proposed, including both local (e.g., soils, grazing, and fire) and global (e.g., CO_2 enrichment) drivers (Ward 2005). For example, Augustine and McNaughton (2004) have shown experimentally for a savanna in central Kenya that the loss of both small selective browsers (e.g., dik-dik (*Madoqua kirkii*)) and large bulk feeders (e.g., elephants (*Loxodonta africana*)) significantly affected the recruitment and establishment dynamics of key encroaching shrub species. Both light and heavy grazing by domestic livestock together with fire suppression also appear important determinants of the rate and extent of bush encroachment (Munyati et al. 2011). Because bush encroachment occurs in both heavily grazed and lightly grazed regions under fundamentally different tenure regimes (Wigley et al. 2010), there is an emerging view that increased atmospheric CO_2 concentrations play a primary role in the process through its influence on the growth rate and competitive ability of encroaching tree species, particularly in terms of their response to fire and herbivory (Bond and Midgley 2012; Buitenwerf et al. 2011). The process of encroachment is also spatially heterogeneous with low-lying alluvial substrates losing cover and hillslopes gaining cover at some locations (Levick and Rogers 2011). Most studies of the impact of bush encroachment have focused on the effect it has had on ecosystem structure and community composition (Table 3).

1.04.5 Invasive Species

Invasive alien species can be defined as those nonnative species that threaten ecosystems, habitats, or species (Convention on Biodiversity 2008). Through their impact on the environment, alien invasive species contribute indirectly to poverty, food insecurity, ill health, and poor water quality (MA 2005) and affect a range of ecosystem services including provisioning, regulating, and cultural services. Vitousek et al. (1997) provide estimates of the number of alien species in Africa (Table 4).

Water quality and supply are critical for human health and well-being, but water resources and their associated ecosystems are also particularly vulnerable to impact from alien invasives. For example, water hyacinth (*Eichhornia crassipes*), a South American native, is a problem in tropical and subtropical waterways globally. Despite being present in Africa from as early as 1900, it is only over the past 30 years that it has become a severe and widespread problem across the continent. The problems caused by this weed are best illustrated by the impacts of *E. crassipes* on Lake Victoria. In the mid-1990s, the lake was infested by up to 20 000 ha of *E. crassipes*, which floated around the lake in huge mats and infested inlets and fishing beaches along the shoreline (Moorhouse and Albright 2002). The impacts of the infestation were extensive and negatively affected agriculture, hydroelectric power generation, fisheries, lake transport, recreation, and water quality and supply for both domestic and industrial use. Kasulo (2000) estimated the annual cost of the hyacinth in Lake Victoria and the other Great Lakes in terms of its impact on fisheries alone at US$71.4 million. Across Africa, the costs may be as much as US$100 million annually (UNEP 2007). Although biocontrol agents have largely brought the weed under control, it remains present, albeit at lower densities, across most of the waterways that have previously been infested.

Table 3 Some of the main impacts of bush encroachment on ecosystem structure and function as well as on the services that ecosystems provide for human well-being in Africa

Country and/or region of study	*Main effect*	*Source*
All savannas and grasslands	Feedbacks to earth–atmosphere systems and regional climates through changes in albedo and reduction in fire emissions	Bond and Midgley (2012)
All savannas and grasslands	Increase in shrub cover, total soil C and N, decrease in grass cover and soil pH	Eldridge et al. (2011)
Namibia	Increase in runoff and lower infiltration of water to subsoils	De Klerk (2004)
Namibia	Increase in woody biomass and availability of firewood	De Klerk (2004)
Ethiopia; Namibia; Southern Kalahari, South Africa	Change in plant species composition and richness, particularly of the grass and herb layer	Angassa (2002); De Klerk (2004); Wasiolka and Blaum (2011)
Southern Kalahari, South Africa; Southern Ethiopia	Change in vegetation structure with knock-on effects for faunal species composition, density, and richness (including arthropods, reptiles, birds and mammalian carnivores)	Blaum et al. (2007, 2009); Spottiswoode et al. (2009); Sirami et al. (2009); Wasiolka and Blaum (2011);
Namibia, Ethiopia	Reduction in carrying capacity for both communal and commercial area cattle production with significant negative impact on livelihoods and agricultural GDP	Hoffman et al. (1999); De Klerk (2004); Gil-Romera et al. (2010)

Table 4 The number of native and alien flora species within various broad regions and countries of Africa

Region/country	*Area (km^2)*	*Number of native species*	*Number of established alien species*	*Percentage of alien species*	*Number of alien species per log (area)*
Western and central Sahara	4 000 000	830	$<$28	$<$3.3	$<$4.2
Tropical Africa	22 300 000	23 500	536	2.2	72.9
Southern Africa	2 693 389	20 573	824	3.9	128.1
Egypt	1 000 250	2015	86	4.1	14.3
Djibouti	23 000	641	44	6.4	10.1
Uganda	236 040	4848	152	3.1	28.3
Rwanda	26 338	2500	93	3.6	21.1
Namibia	824 293	3159	60	1.9	10.1
Swaziland	17 366	2715	110	3.9	25.9
Cape region	90 000	8270	441	5.1	88.9

Extracted from a larger table provided in Vitousek, P. M., C. M. D' antonio, L. L. Loope, M. Rejmánek, and R. Westbrooks, 1997: Introduced species: a significant component of human-caused global change. N. Z. J. Ecol., 21, 1–16., which also lists the original source of the data.

In some cases, changes to the terrestrial system can also have a large impact on water resources. For example, it is estimated that the reduction in surface water runoff as a result of terrestrial woody plant invasions in South Africa was >3000 million m^3, or around 7% of the total value for the country (van Wilgen et al. 2008). Reduction would increase to an average of 46% across five major biomes in South Africa if the potential range of invasive alien plants were to be occupied (**Table 5**). Additional impacts associated with the invasion of woody species include changes to livestock production, biodiversity, fire intensities, increased soil erosion, reduced tourism, and a decline in recreation value. Costs of invasions amount to nearly US$1 billion annually or 0.3% of South Africa's GDP (van Wilgen and De Lange 2011). This could increase to 5% if alien plants were to occupy their full potential range. In a study involving just one of the most serious woody invasives, the black wattle, *Acacia mearnsii*, De Wit et al. (2001) demonstrated that a 'net present cost' of US$ 1.4 billion could be attributed to black wattle invasions in South Africa.

The economic evaluation and quantification of these impacts has been a critical action that has provided support for policies and leveraged funding for proactive management of alien plants in the country. The Working for Water Program is a state-funded response to these studies and aims to increase water supply and associated ecosystem services by clearing alien woody plants from catchments and riparian areas. It has been possible to justify the spending of over US$ 500 million on the program between 1995 and 2004 (Van Wilgen et al. 2008). A novel aspect of the program is that it also runs a parallel social development program that seeks to maximize the opportunities for development of disadvantaged people employed by the program.

Table 5 Potential future impacts of invasive alien plants on key ecosystem services in five biomes of south Africa

	Reduction relative to biome values without alien plants (%)		
Biome	*Mean annual surface water runoff*	*Number of livestock units*	*Biodiversity intactness*
Fynbos	37	67	58
Grassland	50	74	55
Succulent Karoo	60	38	85
Nama Karoo	29	72	96
Savanna and thicket	54	72	61
Average	46	65	71

Compiled from data in Van Wilgen B. W., B. Reyers, D. C. Le Maitre, D. Richardson, and L. Schonegevel, 2008: A biome-scale assessment of the impact of invasive alien plants on ecosystem services in South Africa. *J. Environ. Manag.* **89,** 336–349.

Pimentel et al. (2001) provide an insightful review of the economic costs of the alien invasive species and show that the relative costs are higher in developing compared to developed nations. Using agricultural GDP in 1999 as the benchmark, Perrings (2011) demonstrates using the Pimentel estimates that invasive species caused damage costs equal to 53% of the agricultural GDP in the United States, 31% in the United Kingdom, and 48% in Australia. In contrast, damage costs in South Africa, India, and Brazil were, respectively, 96, 78, and 112% of the agricultural GDP. Since alien species are not more prominent in the latter countries as compared to the former developed nations, this indicates that alien species impact the economy and especially the rural communities of developing nations disproportionately more than those of developed nations. The authors do not attempt to explain this disparity, but it may be related to the less intensive nature of agriculture in the less developed nations and a reduced capacity to directly tackle the invasive problems.

1.04.6 Historical Trajectories and Counter Narratives

1.04.6.1 Temperature and Evaporative Demand

Temperature data for Africa confirm a warming trend of about 0.5 °C for the twentieth century, which is similar to that experienced globally over the same period (Hulme et al. 2001), although there is evidence that this increase in the mean is from increases in the minimum, night time temperature possibly due to land surface change and low level atmospheric aerosols (Christy et al. 2009). Using the Palmer Drought Severity Index as a measure of drought, Dai (2011b) reported a widespread drying trend for Africa over the period 1950–2008, which is consistent with observed decreases in streamflow. This trend is ascribed primarily to the impact of recent warming, especially since the mid-1980s, and not to changes in precipitation. In contrast, studies of direct evaporative demand (as opposed to modeled values) in southern Africa have shown a decrease in pan evaporation (E_{pan}) in the latter part of the twentieth century (Eamus and Palmer 2007; Hoffman et al. 2011). Despite a significant increase in temperature between 1974 and 2005, E_{pan} values in the winter rainfall region of the Western Cape of South Africa declined by an average of 9.1 mm per year, at 16 of the 20 stations investigated, primarily in response to a 25% decline in wind run over the same period. This twentieth century decline in evaporative demand in response to wind stilling has been documented globally (McVicar et al. 2012) and has yet to be satisfactorily explained in terms of prevailing climate science theory (Roderick et al. 2009). It remains a critical issue for African climate research particularly since a decrease in evaporative demand, even with an increase in temperature, would increase plant water use efficiency, NPP, and biomass accumulation (Eamus and Palmer 2007).

1.04.6.2 Precipitation and Vegetation Change

1.04.6.2.1 The Sahel

In the Sahel, for most of the past two decades, annual rainfall totals have been similar to those of the first half of the twentieth century, with a concomitant response in the vegetation (Herrmann et al 2005; Huber et al. 2011). This climate–vegetation response has been tracked primarily by using the NDVI calculated at a spatial resolution of 8 km from the NOAA series of AVHRR satellite imagery (Tucker et al. 2005; Bégué et al. 2011). Excluding the most recent drought in the Sahel and the GHA (Gebrehiwot et al. 2011), the general pattern that emerges for the region and indeed, for most of the world's drylands (Hellden and Tottrup 2008), is that of an overall increase, since the early 1990s, in photosynthetically active vegetation, and by inference NPP (Olsson et al. 2005; Prince et al. 2007). Much of this increase can be explained by either the increase in rainfall (Anyamba and Tucker 2005; Hickler et al. 2005; Hein et al. 2011) or soil moisture (Herrmann et al. 2005; Huber et al. 2011) that has been experienced in the region over this period. While there are some differences across the more than 3 million km^2 that comprise the Sahelian zone (Huber and Fensholt 2011), the general trend of increasing vegetation greenness since 1982 has high spatiotemporal consistency across the region (Hellden and Tottrup 2008) (Figure 8).

1.04.6.2.2 Eastern Africa

As in the Sahel, rainfall in East Africa is significantly influenced by SST over the equatorial regions of the Pacific, Indian, and the southern Atlantic Oceans and the movement of moisture by large-scale atmospheric circulation patterns (Segele et al. 2009). Drought conditions appear to be associated with El

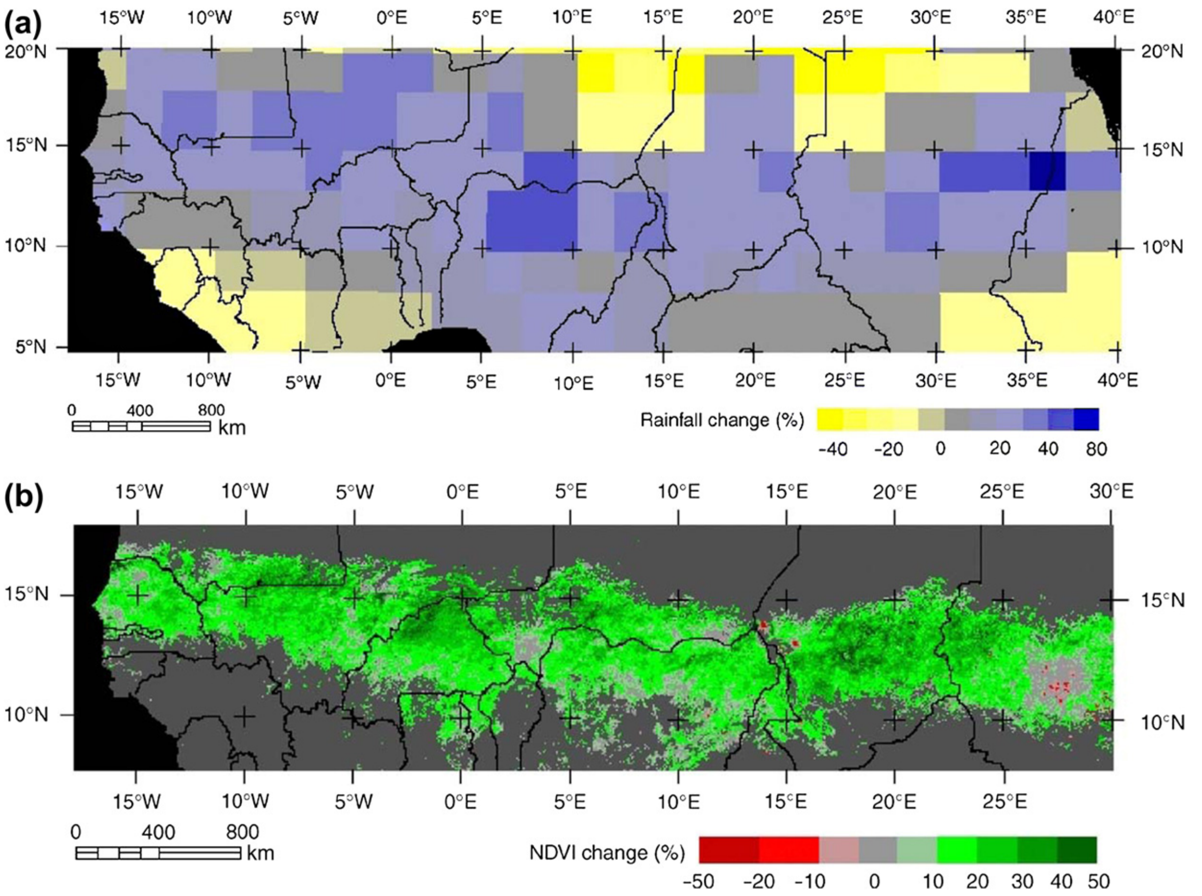

Figure 8 The general increase in monthly rainfall over the period 1982–2003 (a) is primarily responsible for the increase in vegetation greenness (b) observed across the Sahel using NOAA-AVHRR NDVI values. From Herrmann, S. M., A. Anyamba, and C.J. Tucker, 2005: Recent trends in vegetation dynamics in the African Sahel and their relationship to climate. *Global Environ. Change* **15,** 394–404.

Niño conditions and wetter periods with La Niña conditions in the Pacific (Segele et al. 2009). While Ethiopia experienced significant drought in the 1970s and the 1980s (Araya and Stroosnijder 2011), long-term trends in mean annual rainfall do not show a significant decline in the central, northern, and northeastern parts of the country over the latter part of the twentieth century (Seleshi and Camberlin 2006; Cheung et al. 2008). However, drought conditions have prevailed in the southern and eastern regions over the last decade (Gebrehiwot et al. 2011; Rosell 2011).

What has been the response in the vegetation of the region? Repeat photograph studies provide an important counter to the generally catastrophic degradation narrative that has been proposed for Ethiopia (Amacher et al. 2004; Gebresamuel et al. 2010), which suggests that forest cover in Ethiopia has declined from 40% of the land surface in 1885 to as little as 4% by 1985 (McCann 1999). For example, a comparison of 13 photographs from northern Ethiopia, which were first taken in 1868 and then 140 years later in 2008 by Nyssen et al. (2009), show a significant improvement in key ecosystem health indicators such as vegetation cover and soil retention despite a 10-fold increase in the number of people (Figure 9). As in the Machos district in Kenya (Tiffen et al. 1994), the generally positive changes are ascribed to the intensification of land-use practices as well as the widespread implementation of soil and water conservation measures that have occurred in the region since the 1970s.

Similar studies, using repeat photography, have been carried out in other parts of northern Ethiopia but over shorter time periods. For example, Munro et al. (2008) examined 51 matched photographs to document the impact of changing land-use practices in Tigray over the period 1975–2006. Like Hagos et al. (1999) they emphasized the causative links between drought, poverty, war, and land use and how this combination of factors led to widespread degradation in the region particularly during the last few decades of the twentieth century. Their findings suggest that the large-scale SWC measures, started in the 1970s, and that included the building of stone bunds and exclosures, have resulted in a general increase in vegetation cover and a concomitant reduction in soil loss of more than 30% when compared to 1975 levels. Besides the control of soil erosion (Mekuria et al. 2009) and a significant increase in soil organic matter, nitrogen, and phosphorus (Mekuria et al. 2007), additional benefits include improved water flow and a more efficient use of water for biomass production (Descheemaeker et al. 2009). Other repeat photograph studies of landscape change (Nyssen et al. 2008; Frankl et al. 2011) reach similar conclusions and confirm that degradation is reversible, although not without significant effort and sacrifice, particularly on the part of local farmers (Hagos et al. 1999). Success appears greatest where SWC measures provide tangible benefits for rural livelihoods such as an increase in crop yields and where there is also a high demand for agricultural land (Boyd and Slaymaker 2000).

1.04.6.2.3 Southern Africa

The western part of southern Africa, especially the Succulent Karoo biome and southern Namibia, is projected to be most affected by future warming (Tadross et al. 2011). However, analyses of historical climate trends suggest that there has been no significant increase in the incidence of drought in the Succulent Karoo biome since 1951 (Hoffman et al. 2009) and neither do rainfall patterns for the twentieth century appear significantly different than those for the nineteenth century (Kelso and Vogel 2007). While there are differences in long-term precipitation trends between individual climate station records in the Namaqualand region of the Succulent Karoo biome (MacKellar et al. 2007), the vegetation of the ephemeral rives, plains, and slopes appears to have increased in cover over the course of the twentieth century (Hoffman and Rohde 2007,

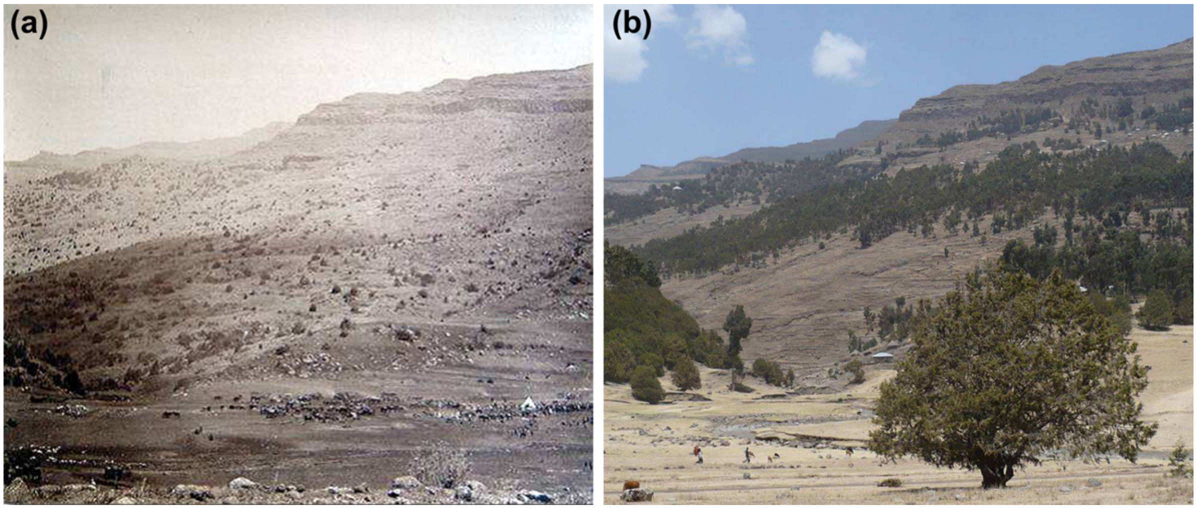

Figure 9 This repeat photograph pair taken in the mountainous Tigray Region of Ethiopia illustrates some of the complex changes in land-use practices and vegetation that have occurred since 1868 (a) when the original photograph was taken and 2008 (b). Settlement density has increased considerably as has the area that has been cropped. Forest cover has increased on the distant hillslopes, which were more sparsely vegetated and more eroded in 1868. However, the erosion gully running through the foreground slopes was not present in 1868. From Nyssen J., and Coauthors, 2009: Desertification? Northern Ethiopia re-photographed after 140 years. *Sci. Total Environ.*, **407,** 2749–2755, Supplementary data.

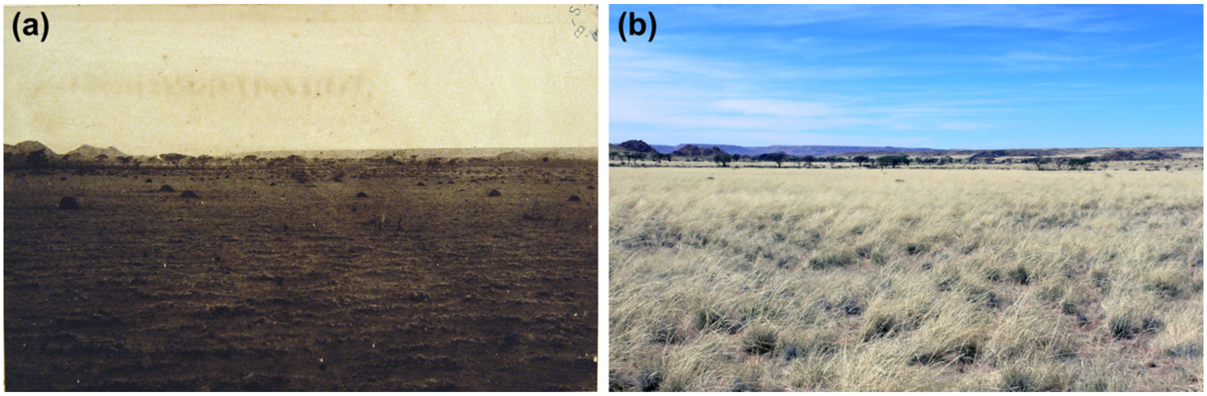

Figure 10 Vegetation change at Kunjas Farm in southern Namibia near Helmiringhausen between 1876 (a) and 2008 (b). While there has been an increase in the ephemeral grass component, the long-lived *Acacia erioloba* trees have remained stable over time. Unpublished photograph reproduced with permission from south African Libraries and Rohde and Hoffman.

2011) even under the heavy grazing regime within the region's communal areas (Rohde and Hoffman 2008). The primary reason for this is the abandonment of agriculture in marginal environments, the switch to commercial sheep breeds, and the associated reduction in stock numbers in the latter part of the twentieth century (Hoffman and Rohde 2007). Spatial patterns and temporal trends in NDVI for the period 1981–2003 confirm that there has been an increase in climate-adjusted NPP in the western part of southern Africa (Bai and Dent 2007).

The arid and semiarid regions of southern Namibia have also been remarkably stable over more than a century, and little sign of aridification, as projected for the next 40 years (Midgley et al. 2005), is evident in any of the nearly 50 repeat photographs taken for the region, which span more than 130 years of environmental history (Rohde and Hoffman 2012). While ephemeral grasses have fluctuated in response to seasonal changes in rainfall there is no evidence of widespread degradation associated with arid shrubland expansion at the expense of grassy savanna vegetation (Figure 10).

1.04.7 Future Research Challenges

Environmental change in Africa is influenced by a complex suite of direct and indirect drivers operating and interacting at different spatial and temporal scales (Dawson et al. 2010). Their impact on ecosystem processes and states has important consequences for the services provided by the environment and for human well-being. This review has highlighted the nature, extent, and impact of environmental change on the continent and has emphasized the considerable uncertainty that exists in future projections. Such uncertainty will be compounded by the rapidity of social change, including urbanization and land tenure reform (UNECA 2004). To better adapt to this change we need to address the following key issues.

- Improve our understanding of the extent and pattern of past environment change in Africa over both short (years to decades) and long (centuries to millennia) temporal scales and how it has affected the supply of critical ecosystem services and human well-being over time;
- Develop a more comprehensive analysis of how direct and indirect drivers of environmental change interact to influence ecosystem services;
- Evaluate more comprehensively the costs and benefits to society of environmental change both in the present and future and explore the trade-offs that are needed between ecosystem services (e.g., between carbon sequestration, water provision, and biodiversity (Van Wilgen et al. 2008)). To this end, greater investment in scenario planning will be necessary, but these need to document the entire spectrum of what is possible;
- Assess the predictability and, if possible, improve our ability to skillfully forecast future changes in the environment and their implications for different communities, economies, and societies living in different parts of the continent;
- Build a stronger interdisciplinary network within Africa in collaboration with international colleagues and with strong political and institutional support so that problems and solutions can be more easily shared between regions.

Glossary

Anthropocene A recent period of Earth's history, during which the combined influence of one species – *Homo sapiens* – has acted with sufficient power and scale to change the Earth system.

Biodiversity Abundance of biological variety.

Biophilia Psychological connectivity, including affection and love, felt and expressed by some humans toward other forms of life.

Climate change Alterations of regional and local climate, even statistically.

Ecocentrism A philosophical and attitudinal perspective that gives high value to biological and natural processes; at its extreme, this could lead to the detriment of the well-being of some human beings.

EcoHealth A term that indicates links between human and ecological well-being.

Ecosystems Basic units of nature within which living organisms continually interact with nonlife forms, whose boundaries are arbitrary, and that exist in dynamic equilibrium.

Ecosystem services The benefits provided to humans and other species by nature; examples range from obvious (oxygen, food, water) to subtle (regulation of the carbon cycle) and psychological, including aesthetic beauty.

Green space Parks, playing fields, trees, watercourses, woods, and gardens – areas that are not predominantly paved or used for buildings; generally applied to otherwise urbanized environments.

Human well-being A state of existence in which the basic material needs of people are met and they have freedom and choice, good social relations, personal security, and reasonable health.

Sustainability A process of living within the limits of available physical, natural, and social resources in ways that allow the living systems in which humans are embedded to thrive in perpetuity.

1.05.1 Introduction: Our Growing Disconnection from Nature

More than three million years ago, tool-using hominids (*Australopithecus afarensis*) in modern-day Ethiopia were cooperatively shaping and transporting specialized cutting stones at least 6 km from their source (McPherron et al. 2010). Palaeontologists are confident about this because of knife marks found on several fossilized ungulate bones in an area devoid of suitable material for making stones able to cut such bones. At that time of prehuman development, it is obvious that everything essential to life for these hominids came from the environment – sunlight, stones for tools, animals to hunt, water to drink, air to breath, plants to eat, and probably trees to shelter in. However, it is unlikely that these hominids, who walked upright, could conceptualize this intimate dependence on nature, as cognition is considered, at least in primates, to have coevolved with language, learning, and sociality. Although we can deduce that *A. afarensis* could communicate sufficiently well to hunt cooperatively, it is believed that their capacity for speech as we know it of any kind, let alone discussion, was limited by the presence of air sacs in their larynxes. (These are anatomical structures still found in most of the great apes that disappeared from *Homo* ancestors at least 600 000 years ago. Great apes communicate using a combination of vocalizations, expressions, and gestures, but their capacity to communicate possible complex thoughts is considered to be limited.)

The time by which hominids developed the capacity for complex speech and cognition is uncertain and disputed, but it is certainly ancient. At some stage in this evolution, modern humans or their ancestors must have developed concepts about the environment, its value as a resource provider, and their place within it. This can be deduced by the importance given to land and other environmental elements, such as totem species by indigenous populations, both ancient (Berkes et al. 1998) and modern (Nettleton et al. 2007). Such perspectives include an integrated understanding of the relationships between land and human health.

In 2010, Jacinto Zarabata visited the United Kingdom. He was a spokesperson for the spiritual leaders of the Kogi people, who live in Colombia. The Kogi are making a movie about their way of life in an attempt to warn people in the West ('little brother') to cease destruction of the planet before it is too late. When interviewed about his impressions of London he said:

> "The first thing that is noticeable to me is that this is still the world," he says. "What's visible is construction, what you have made. This is not something we, the Kogi, are used to seeing. You give precedence to the use of a thing rather than its source. That's the intellectual error. Ultimately, it's all nature" (Barkham, 2010).

Earlier, the U.S. ecologist Aldo Leopold wrote (using land as a synonym for ecosystems) in his 1949 classic, *A Sand Country Almanac with Essays on Conservation from Round River* (Foreword, p. viii):

> We abuse land because we regard it as a commodity belonging to us. When we see land as a community to which we belong, we may begin to use it with love and respect. There is no other way for land to survive the impact of mechanized man, nor for us to reap from it the aesthetic harvest it is capable, under science, of contributing to culture.

In this, the second decade of the twenty-first century, more than half of humanity live in urban environments, including hundreds of millions in slums, suburbs, and high-rise apartments. A recent United Nations Children's Fund (UNICEF) report states that one in three urban dwellers lives in slums. In Africa the proportion is almost double (UNICEF 2012). Slums are areas of dense, poor-quality housing, often with limited green space and few trees. The dominant nonhuman mammal may be a rodent carrying diseases such as plague or leptospirosis that can infect humans. In such places, the most common insect encountered may be a mosquito, breeding in puddles and water containers. Such limited and hazardous forms of exposure to nature are unlikely to benefit psychological health. There is increasing recognition of the multidimensional vulnerability of populations who live in slums to climate and climate change, including to floods and food disruption (see 1.26 Case Studies: Addressing Vulnerabilities and Reducing Risks – Vulnerable Countries).

More humans are thus less exposed to rural surroundings and 'wilderness,' that is, uninhabited areas that appear little altered by human action. In many countries, too, rural landscapes have been massively transformed. An example is monocultures, such as corn fields, rice paddies, and palm oil plantations. Yet humans remain part of the natural world, completely dependent on both renewable and nonrenewable natural resources for survival. Even dwellers of high-rise apartments need food, water, and air. Such buildings are made from earthly materials, whether stone, concrete, steel, bamboo, or wood. Plastics, made from petroleum, are fossilized biota.

A psychological distancing from nature has accompanied this physical separation. Until about 1850, in many European cultures, it was accepted and even prestigious (for those able to afford it) to carve animals at the table. Draft animals, such as horses and donkeys, were common in towns, and the countryside was never far away. Indeed, if not living on the land, many had relatives who were farmers and were therefore exposed to rural living. Until comparatively recently, it was also not unusual for humans to be directly involved with the raising and slaughtering of such animals, as is still the case in most parts of the world. However, this daily reminder of our dependency on nature has slowly waned, especially among the most wealthy and influential global class. This class, which disproportionately influences policy (Butler 2000), is arguably the group most distanced from the earlier mentioned sense of dependency on ecosystem services. Although many in this highly urbanized group enjoy the relatively privileged experience of psychological benefits arising through frequent contact with green spaces, such as by living in leafy suburbs, too many of 'the 1%' experience a psychological disconnect with the poor. Surveys suggest that an increasing number of children do not realize that some of their food is grown in the ground. Petting zoos of farm animals are now very popular.

1.05.2 Psychological Benefits of Exposure to Nature

These observations may seem obvious to readers who feel strongly connected with nature, who experience and express what the sociologist and psychoanalyst Erich Fromm called biophilia (love of life), a concept further developed by the biologist E. O. Wilson. Richard Louv has coined the term *nature deficit disorder* to describe how people with limited contact with nature experience increased rates of symptoms, including behavioral disorders, anxiety, and sadness (Louv 2008). Louv, a journalist, is far from alone in this emerging field of psychological health.

The desert cultures of North Africa and Arabia depend on oases not only for water, food, and shade but also for something harder to quantify: a respite from the monotony of sand. Images of paradise always include gardens. The Garden of Eden is a foundational myth for the three Abrahamic faiths, followed by at least half of modern humanity. Hindus and Buddhists have similar visions of verdant, vibrant, and desirable places of natural abundance and interspecies harmony. This multicultural evidence of yearning for nature seems to reflect a deep-rooted recognition of its therapeutic, nurturing value. Qualities that exceed the physical nurturing of food and shelter seem to reach into the human spirit. From quite a young age, all humans know that they will die. Contact with nature (or for some, perhaps stargazing) seems to provide solace, a reminder that we are part of a much larger system that will endure, even if we cannot.

Recognition of the intrinsic value of healthy ecosystems may occur even without the intellectual understanding of the mechanisms involved, as though this valuing transcends the cognitive and lives in the amygdala, the limbic system. Neuroscience has identified these areas of the brain as the seat of fear and anxiety. These primal brain functions emerged very early in animal evolution and provide an important protective mechanism. Strategies within the suite of complementary medical therapies attempt to target the limbic system. They seek to quell feelings of fear and anxiety and to promote a sense of positive well-being by triggering deep limbic senses via music and aroma therapies. Neuroscientific research may, in future, determine that the sense of well-being and comfort humans attribute to the connection with nature is linked to the emotional neuropathways of the limbic system. It is also noteworthy that humans seem most attracted toward healthy ecosystems (Rosnäs et al. 2011), including oceans, and, conversely, feel repugnance and disgust when exposed to rotting, decaying, and contaminated ecosystems that appear unhealthy or unsafe. Hence, it is biologically plausible that such a strong self-protective mechanism evolved to become entrenched in our primitive brain, and it is difficult to access or explain by intellect.

Many humans form strong emotional bonds with pets, and some also feel affinity and attachment to wildlife. This regard is not necessarily limited to animals with which they occasionally interact, but also extend to animals, species, and even entire ecosystems that they never visit. This is evidenced by the growing international phenomenon of support for organizations that try to protect wildlife and biodiversity and also by the popularity of documentaries about nature. It is also evident in terms such as *ahimsa* (reverence for life in Sanskrit) and in the Chipko movement in India, which sought to protect forests in parts of India. In Thailand, some Buddhist monks ordained trees in an effort to protect their diminishing forests. The growing global Green political movement is also strongly motivated by a consciousness of an endangered natural world. Several relevant international professional networks work in the area of ecology and health, such as the International Association for Ecology and Health, the International Society of Doctors for the Environment, and the Global Ecological Integrity Group.

In the 1950s, leading microbiologist and later planetary ecologist René Dubos commented on the reduced human contact with nature that he foresaw evolving, especially in urban areas. Dubos speculated that this would trigger a demand for artificial forms of stimulation, including stimulation through an increased use of drugs. It is possible that Dubos may also have anticipated a growth in electronic stimulation as partial compensation for the loss of contact with nature: the early forms of electronic games and virtual reality were evolving when Dubos was still alive.

The three-dimensional film *Avatar* (2009), which depicts a highly creative universe of synthetic ecosystems and endangered indigenous populations, was a worldwide hit, including briefly in China until it was banned. In the late 1990s, millions of people, mainly in East Asia, formed strong emotional bonds with an electronic toy called the Tamagotchi, which was programmed to need regular tending, including feeding, to prevent it from 'dying' (Levy 2007). Both cases seem to illustrate a yearning for a greater sense of connectedness with other forms of life, be it an animal, a plant, or a human, in a part of the world where children have become uncommon and siblings rare.

Although with a small sample and uncontrolled for socioeconomic status, an early study found that surgical patients recovered faster if they could see out through a window at a natural scene than similar patients in the same hospital with less salubrious views. More rigorous scientific literature in this growing field supports the intuition that exposure to nature brings mental health benefits (Maller et al. 2006). Although earlier studies appear to have commented little on social class, a recent Dutch study found that green space is positively correlated with self-perceived health and mortality and not confounded by social class (Maas et al. 2009).

A confounding explanation for why time passed in nature can be therapeutic is that, during such times, people are distanced from their daily stresses and strains. Many people spend rejuvenating time at the beach, in the countryside, or just walking in the mountains for at least a part of their holiday. It could be argued that recreation are the sole cause of such renewal, irrespective of location. However, if this were the only explanation, then why would so many people be drawn to nature? The desire for solitude is an unconvincing single explanation. Henry Thoreau, whose book *Walden* was extremely popular in the United States in the nineteenth and twentieth centuries, appreciated seclusion. However, Thoreau is remembered principally for his vivid appreciation of nature (Cafaro 2001).

An additional confounding explanation is exercise, which often accompanies exposure to nature. Exercise (especially for people who are primarily sedentary) is mood elevating, even if it is done in a gym or a swimming pool. People from urban backgrounds, who spend more time with nature, are also likely to come from a higher ranked socioeconomic group and therefore may be systematically different from the general population. However, proponents of the mental health benefits of nature argue that the benefits exceed that which is plausible because of these other factors. These benefits include reduced stress reduction, faster recovery from mental fatigue, and a freshened outlook on life. Less certainty exists that benefits for behavioral disorders outweigh socioeconomic disadvantage (Maller et al. 2006).

There is growing recognition that mental disorders, especially depression and anxiety, cause an immense burden of disease (see 1.18, Mental Health and Stress-Related Disorders). It is plausible, therefore, that more contact with nature, especially for urban dwellers, will greatly benefit global health (Rosnäs et al. 2011). Much remains poorly understood. For example, it is plausible that people will benefit more from exposure to a more biodiverse green space than to a green monoculture. Support for this hypothesis exists from studies undertaken in Sheffield, England, a city of about 500 000 people. Investigators reported a positive correlation between psychological well-being and higher levels of biodiversity (plants, birds, and butterflies) among the 312 people they interviewed, when they were exposed to the city's various gardens (Fuller et al. 2007). The socioeconomic status of their informants was not reported.

It is plausible that the more biodiverse parks are in more affluent areas and that interviewees experiencing such parks are better off financially. However, it could be true that people from more disadvantaged areas would gain as great a benefit, or even greater benefit, were they to be more exposed to this biodiversity. Other workers have recently proposed an alternative mechanism, linking psychological well-being with biodiversity and other indicators of ecosystem 'health,' such as ecosystem resilience, organization, and vigor (Dean et al. 2011). Where exposure to nature is limited, humans also gain pleasure and other psychological benefits from contact with fish tanks and from representations of nature, such as photographs, paintings, and computer screensavers. The eminent environmental historian of China, Mark Elvin, stated that in some cases individual trees are venerated as symbolic representations of entire ecosystems.

1.05.3 Sacred Groves and Risks to the Sacred

Humans thus desire, and perhaps at a cellular level *require*, far more from ecosystems than food and water. Most visitors to the diplomatic area of New Delhi are struck by the leafiness of the suburb. In the center of this immensely crowded though extensively forested city, some of the most exclusive hotels maintain small but exquisite gardens. Wealthy people appreciate and can easily afford contact with nature. The urban poor might crave such contact, too, especially if associated with leisure. They survive, in a fashion, without it, but few thrive for it.

Many individuals and groups worldwide, even those who consider themselves 'nonindigenous,' have long recognized the value of certain charismatic and sacred species and groves. The bald eagle is the national bird of the United States. Numerous families, guilds, cities, and nations symbolically honor animals and birds in their flags, logos, and coats of armor. Many cultural symbols, decorations, and ceremonies rely on nature, from sacred plants, fungi, and animals to such seasonal displays as animal migration.

This modern era phenomenon of urban disconnection from nature is significant because the fraction of humanity most separated from nature also has the greatest economic and political influence over the human future. For such a population, perhaps about one billion of the seven billion people alive in this twenty-first century, food commonly is purchased wrapped in plastic or otherwise disguised from its plant, animal, or fungal source. Processed food is increasingly blended with synthetic ingredients, such as preservatives, colors, and flavors. Even cooking is a fading art for some groups.

Food, even if grown hydroponically (i.e., with no soil), was once alive. In March 2012, researchers at Maastricht University reported growing small pieces of muscle about 2 cm long, 1 cm wide, and 1 mm thick in a petri dish. Team leader Professor Mark Post suggests that, in 10 years' time, the commercial production of synthetic meat could reduce the environmental footprint of meat by up to 60% (Ghosh 2012). Currently, all the animal products that humans ingest, consume, or rely on (such as leather and draft animals) are sourced from species that, like us, have the capacity for movement, feeling, and emotion (de Waal 2009), if not complex thought. These animals also require food, water, shelter, and energy. Even if artificial meat could be commercially synthesized and it could deliver the equivalent in micronutrients, it would still require inputs such as energy and raw materials from nature.

The apparent separation from nature by decision makers has another dimension. Many policy makers and corporate leaders behave as if they do not think that civilization is ultimately dependent on natural resources. As discussed, although some of them also appear to express limited biophilia (Ted Turner, founder of CNN, is a noted exception; among his efforts is the preservation of large sustaining herds of bison), many of the most privileged and powerful do experience firsthand exposure to nature. Some people seem to experience an additional form of separation, such as young Wall Street traders. This separation can be expressed perhaps as insufficient identification not only with nature, but also with other people, especially the poor and disempowered. But there is a third element here. Politicians and decision makers in all but the worst autocracies do heed public opinion. It follows, therefore, that not enough people, whether in wealthy economies or countries such as Europe, Japan, the United States, or Australia or in poorer countries including China and India, fully appreciate the collective danger that humanity faces this century and perhaps in the next as we pass through a narrowing funnel of risk.

Surveys consistently report sentiments at least moderately sympathetic to the environment across differing nations and demographic groups (Dunlap et al. 2000). Nevertheless, contrary to these findings, a comparatively *low* commitment to ecological and environmental protection can be deduced by our collective behavior and national policies. This value system has been dubbed the dominant social paradigm, distinct from an environmental paradigm (Dunlap et al. 2000).

From an ecosystemic perspective, there is a relentless global drive toward increased provisioning of ecosystem services, especially to feed the world's population. This occurs at a cost to biodiversity and other vital ecosystem components and services, such as carbon regulation and landscape 'health.' Reflecting this dominant social paradigm, existing geopolitical systems that value the accrual and control of money-generating sources above all else are destined to undervalue natural resources – to their detriment.

Unfortunately, this manifestation is often combined with the neoliberal view that natural bounty is limitless because it is perpetually and perfectly regenerative; therefore, exploitation can persist at higher and higher intensities without ever depleting nature's capital. The more skeptical view is that underlying such ravages of exploitation is the motive pervasive in the Tragedy of the Commons (Hardin 1968), which may be expressed simply as follows: 'because common goods are there for the taking, I must maximize my personal gain before the chance is lost to others.'

This transformation is driven at a deep level by two mechanisms: the enormous expansion of human populations since the last century and, even more fundamentally, humanity's conceit engendered by its industrial ingenuity and seeming mastery of energy, an illusion perpetuated by the temporary abundance of oil and other fossil fuels (see 3.4, Vulnerabilities of Energy Resources and Resource Availability – Fossil Fuels (Oil, Coal, Natural Gas, Oil Shale)). There are now numerous warnings that these processes are unsustainable, thus placing not only human health and well-being, but also planetary ecosystems and civilization itself at increasing risk (Butler and Weinstein 2011). This risk is likely to manifest through multiple pathways, including the emission and accumulation of greenhouse gases, aerosols from industrial and vehicular emissions, and biomass burning, and from land use change including deforestation (National Resource Council [NRC] 2005). Diverse, adverse human feedbacks to emerging scarcities, including large-scale conflict, appear all too plausible (McMichael 2012). Indeed, such consequences have been conceptualized as 'tertiary' effects, in contrast to more direct effects that are smaller in scale (Butler and Harley 2010). The 2003 heat wave in Europe – at least partially, a primary effect of climate change – killed as many as 70 000, mostly elderly, people (see 1.15, HeatRelated Morbidity and Mortality). Flooding in Pakistan in 2010 – another primary effect – temporarily displaced 20 million people (see 1.17, Climate, Precipitation, and Flood Hazards). Large as these events were, their scale may be dwarfed by tertiary effects, such as the permanent displacement of tens of millions of people from the coastline around the Bay of Bengal and other low-lying regions. This seems inevitable if greenhouse gas emissions continue on their current trajectory (see 1.5, Sea-Level Rise and Coastal Inundation).

Although the proportion of humans involved in war has declined (Pinker 2011), this has coincided with improved living standards largely underwritten by cheap fossil fuel energy. As these supplies become depleted, the price of food and other necessities will rise further, driving competition and discontent. Unless these trends can be urgently reversed, it seems very likely that humans will again turn to large-scale violence, as was the case in famine-affected parts of northeastern Africa in 2011. Violence is of course not restricted to low-income countries; it is now widely accepted that resource scarcity (oil) was a fundamental reason for the invasion of Iraq by the United States and her allies. Other plausible 'tertiary' effects of resource scarcity are famine and nuclear war, worsened by the protean manifestations of climate change and ecological degradation.

1.05.4 Ecosystem Services

There are several ways to conceptualize the relationship between human well-being, human health, and nature. The most common classification is that established by the Millennium Ecosystem Assessment, an international collaboration of more than 1200 scientists, collating and assessing relevant literature for a four-year period (2001–05). This group identified four main forms of ecosystem 'services': provisioning, culturally enriching, regulating, and supporting (Millennium Ecosystem Assessment 2003; Butler and Soskolne in press) (see Table 1).

The concept of ecosystem services is not universally accepted. A major criticism is that it is too human-centered; some ecologists prefer 'ecological functions,' probably because the word 'function' is perceived as less anthropocentric. In fact, association with economic terminology was deliberately undertaken in the hope that it would better convince economically rational policy makers that the benefits of ecological protection reached beyond that of nature conservation and protection to encompass and influence human well-being.

From an extreme biocentric (deep ecology) position, the intrinsic value of an algal bloom, jellyfish swarm, or school of cod may be considered proportional to its biomass; however, such arguments can merge with ecofascism and sophistry.

Provisioning ecosystem services refer to the functions by ecosystems, whether anthropogenic or largely free of human influence, that result in the material products desired and valued by humans, such as food, fiber, timber, and medicinal products. Some plants are used for dyes and other products for insulation, protection, decorations, and status. Examples include wool, hides, feathers, and shells. *Culturally enriching* ecosystem services have been partly discussed earlier. Elements include the knowledge and existence of charismatic species and the benefits to many humans that flow from contact with comparatively wild spaces. The third category is of *regulating* ecosystem services that produce benefits to humans and other species and are less recognized than provisioning services. Examples include the stabilization of slopes against erosion by forests and the cleansing of polluted water by passage through a filtering wetland. Another example is the regulation of Earth's climate by its global suite of ecosystems, a service now severely disrupted by human actions (see Vol. 4, Vulnerability of Ecosystems to Climate). Finally, *supporting* ecosystem services refer to functions generally hidden or invisible, such as the recycling of nutrients within soil by the actions of bacteria and billions of other organisms. Bacteria and other organisms living within the gastrointestinal tracts of animals, including humans, also perform poorly understood supporting ecosystem services. Provisioning and regulating services are discussed in more detail later in this chapter. Culturally enriching services have

Table 1 Typology of four ecosystem services, using a classification developed by the Millennium Ecosystem Assessment

Ecosystem 'service'	*Example*
Provisioning	Food crops (e.g., wheat fields, rice paddies, market gardens), fiber crops (cotton, bamboo), biofuels (e.g., from corn and sugar cane), animal products (e.g., sheep flocks, chicken farms), aquaculture ponds (fish stocks), freshwater, medicinal products (e.g., codeine, pyrethrum), mangroves (fish nurseries)
Regulating	Forests on slopes that stabilize soil, lessening erosion; coastal protection from storms and (partially) tsunamis (carbon stabilization); some cases of infectious disease limitation (e.g., Lyme disease, malaria in some cases, onchocerciasis)
Culturally enriching	Inspiration (charismatic landscapes and species, e.g., coral reefs, tiger reserves, old-growth forests), spiritual refreshment (sacred groves), religious observation, ancestral links, ceremonial decorations (red ochre, bird of paradise feathers)
Supporting	Soil fertility and nutrient recycling (microorganisms, earthworms, fungi), pollinators (insects, birds, bats), insect control (birds), seed dispersers (bats, birds, apes, elephants), detoxification, and nutrient recycling

Millennium Ecosystem Assessment, 2003: Ecosystems and Human Well-being. A Framework for Assessment. Island Press, 245 pp.

been discussed earlier, mainly in relation to psychological well-being. Some aspects of supporting services are now discussed in relation to biodiversity.

1.05.5 Biodiversity, Ecosystems, and Ecosystem Services

Biodiversity is a contraction of *biological diversity*, a term now about 30 years old, whose roots can be traced even earlier (Hutchinson 1959). Biodiversity and ecosystems interact with each other. For example, the distribution of species helps maintain ecosystems; intact ecosystems help conserve biodiversity. Ecosystems are in some ways analogous to information technology operating systems: species are the various files found on separate computers. Through competition, populations are generally kept in balance at a level their niche can support. Interruptions to important levers in maintaining this balance – such as loss of predators and other keystone species like carnivores and herbivores – can have profound effects on ecosystems. An example is the absence of predators because of extinction or absence, as can occur on islands, which is likely to lead to high populations of herbivores and consequent denuding of fodder, such as grass and shrubs. In some cases, this unchecked population increase can rebound to cause mass herbivore mortality because of starvation.

Similar phenomena can occur in the oceans, with nonlinear responses following an apparently small change. For example, variations in ocean temperatures have been predicted to alter many marine populations, including the sea star *Pisaster ochraceus*, which feeds on mussels. In turn, reduction in this keystone predator species reduces biodiversity, leading to an effective monoculture of mussels (Sanford 1999).

Disease can dislodge the ecological balance. An example is the epizoonosis (Epizoonosis is a disease that only affects nonhuman animals) rinderpest, commonly called cattle plague. In the late nineteenth century, rinderpest entered northeastern Africa via imported cattle and spread rapidly. This epidemic led to a massive loss of herbivorous animals, both wild and domesticated. With few animals grazing young tree saplings, trees took over the plains. Many farms were abandoned after the Black Death in Europe, which killed up to one-third of the population. Consequently, nature advanced. Forests reclaimed part of the landscape. Villages advertised for settlers to repopulate the districts.

Rinderpest, although it did not kill humans directly, also had profoundly adverse effects on human health. In the nineteenth-century African outbreak, loss of domesticated oxen reduced plowing and thus agricultural productivity. Infection in wild species lowered the effectiveness of hunting. Worsened by periodic droughts and exacerbated by smallpox, as many as one-third of the Ethiopian population and two-thirds of the Maasai people of East Africa died during a period still remembered by the Maasai as the *Emutai* ('to wipe out') (Gillson 2006). These cases also sound a warning over excessive genetic homogeneity. Deliberate breeding strategies can reduce resistance not only among animals, but also among plants.

There is a complex and as yet poorly understood relationship between biodiversity and ecosystem services (Lovejoy 1994). This speculation dates at least to Charles Darwin, although Darwin would not have used either term. It has been suggested that more biodiverse ecosystems have greater functional capacity, including for roles such as pollination, nutrient absorption, water purification, grassland productivity, and rice crop yields (Zhu et al. 2000). In some cases, diversity is beneficial because it leads to a greater likelihood of naturally occurring biological pest controls. Organic farming systems have a higher capacity to cleave protein and organic phosphorus and higher overall microbial activity than do the conventional systems (Maeder et al. 2002). Monocultures, in contrast, rely heavily on chemical pesticides and fertilizers, both of which can harm health (Hanna 2005). Monocultures are often preferred because of their generally higher yields (Maeder et al. 2002), yet their optimal performance requires favorable conditions and high-input agronomic systems. They typically do not perform well in marginal environments or without those external inputs of chemicals and fertilizers (Murphy et al. 2005). However, the specific biological mechanisms by which biodiversity influences many of these functions remain uncertain, and unfortunately, this has led to some resistance to value diversity for its own sake (Cardinale 2011).

In Western Australia, the brush-tailed bettong *Bettongia penicillata* improves the absorptive capacity of soil through its habit of digging for fungi (Garkaklis et al. 1998). Many species, including mammals, birds, and bats, assist in seed dispersal. Insectivorous bats are important regulators of insect populations. White nose syndrome, a devastating fungal disease decimating little brown bat populations in several northeastern states of the United States, threatens to increase the population of numerous insects, placing food security at further risk (Frick et al. 2010).

It has recently been recognized that some species of ants and termites have a similar function to earthworms in enhancing soil fertility. Their tunnels improve water infiltration, aeration, and soil nitrogen content. A recent field experiment has shown that the presence of ants and termites increased wheat yield by 36%. Such species may be especially important in arid climates (Evans et al. 2011).

Recent modeling work has shown that a process called 'niche partitioning' among species of algae can increase the uptake and storage of nitrate (Cardinale 2011), an important water pollutant. An implication is that biodiversity may buffer natural ecosystems against the ecological impacts of nutrient pollution (Cardinale 2011). Biodiverse ecosystems will also be more resilient to climate shocks than low-diversity systems.

1.05.5.1 Ecosystem Theory: History

The original scientific definition of an *ecosystem* as a basic unit of nature dates to 1935. Arthur Tansley coined this term, echoing the Russian scientist Vladimir Vernadsky (of whose work he was probably unaware) in appreciating that there is continual interaction between life and nonlife (the abiotic). Tansley also recognized that the boundaries between ecosystems are arbitrary but still useful for the analysis.

The *system* part of the term is linked to holism, synthesis, thresholds, phase change, emergence, and self-organization. Lovelock extended these ideas, conceptualizing the Earth system as a self-regulating, self-organizing entity in space (albeit with no planetary consciousness) (Lovelock 1979).

The idea of planetary homeostasis follows the nineteenth-century French physician Claude Bernard's recognition of homeostasis within a body. This is similar to the ancient Ayurvedic concepts of physical balance.

Recognition of the planetary impact of our species is fairly new, expressed by Nobel Laureate Paul Crutzen's call for declaration of the 'anthropocene' and its 'acceleration' (Steffen et al. 2011). Crutzen suggested that this new epoch started around 1750, at the dawn of the Industrial Revolution, when humans started to substantially alter the environment, by increasing the concentration of greenhouse gases, especially carbon dioxide (CO_2). Other gaseous and aerosol emissions also changed, as a growing population, assisted by unprecedented access to energy, formed a vastly altered landscape, by irrigation, deforestation, and grazing. Others have pointed out that humans have had large-scale impacts on the environment and its ecosystems for far longer, such as by the hunting and extinction of many forms of megafauna (Caro et al. 2011) and by deforestation and early farming (Caro et al. 2011; Ruddiman 2004). Previous academics also recognized the planetary scale of humanity's impact, including Marsh (1864) and Sherlock (1922).

1.05.5.2 Provisioning Ecosystem Services: Food

The consumption of organisms is essential to nutrition and health. Currently, the world produces enough food to supply adequate calories for about nine billion people, were this evenly distributed. In fact, roughly a billion people are classed as 'hungry' by the Food and Agricultural Organisation of the United Nations, while another two to three billion are recognized as micronutrient deprived, although they ingest sufficient energy and protein so as not to be grouped as 'hungry.' Climate change, in combination with other limits to growth, is likely to worsen food insecurity (Butler 2010a) (see 1.14, Climate Change Health Effects, Risks, and Impacts with Focus on Foodborne Diseases and Nutrition and Vol. 2, Vulnerability of Food Resources to Climate).

Human ingenuity, effort, and tools have radically transformed a substantial and increasing fraction of Earth's landmass and sea. Although hardly 'natural,' in this twenty-first century, most food is grown in these modified, anthropogenic environments, such as wheat fields, rice paddies, palm oil plantations, and fish farms. Intensive farming of both plants and animals appears inevitable if we are to feed the global population. However, others argue that the displacement of peasant farmers by corporations has greatly worsened food security (McMichael 2009).

1.05.5.3 Intensive Animal Farming

Billions of animals are raised and killed each year to feed people. Most of these creatures live in highly transformed ecosystems, sometimes called industrialized farms. Their conditions are kept from public view, helping to reduce community outcry. Living conditions for animals in such places are as little known to most people of the twenty-first century as the rat-infested slaughterhouses in Chicago, graphically described by Upton Sinclair in his 1906 book, *The Jungle*. Mainly grown this way are chickens, pigs, cattle, and several species of fish and shellfish. Small numbers of exotic mammals are also grown intensively, including racoon dogs and palm civets. There is increasing concern that intensively farmed animals can play an important part in the generation of unusually virulent zoonotic pathogens, such as highly pathogenic avian influenza (H5N1) and swine flu. There is also evidence that larger rather than small piggeries in Malaysia were associated with the 1997–98 outbreak of Nipah virus, a batborne pathogen, which killed more than 100 farmers and led to the culling of more than one million pigs. Ongoing pressures to further intensify farming practices to feed growing populations fuel this concern.

To date, most diseases associated with intensive farming have caused high animal rather than human mortality. However, high animal mortality, both through disease and control measures (to date, most notably for avian influenza, foot and mouth disease, and Nipah virus), can have substantial adverse effects on human health through loss of livelihood and the psychological trauma of culling animals, especially if they appear healthy (Zinsstag and Weiss 2001). Considerable anxiety remains that some of these diseases could affect humans in large numbers. Most anxiety concerns the possibility that highly pathogenic avian influenza (H5N1) will develop easy human transmission with high resultant lethality, although this is disputed (Palese and Wang 2012). Other concerns are for Sudden Acute Respiratory Syndrome (SARS), H1N1 influenza (the so-called swine flu), Nipah virus, and *Streptococcus suis*.

Intensive animal farming is also associated with a high climate impact in three main categories. First, the ongoing expansion of animals in 'landless farms' requires growing and shipping large amounts of feed, especially grain and soy. This stimulates the ongoing clearing of land, which also releases greenhouse gases, mostly CO_2. Second, digastric animals (cattle, sheep, and goats) release large volumes of methane (CH_4), a greenhouse gas that is far more potent per molecule than CO_2 (Shindell et al. 2009). The atmospheric life of CH_4 is much shorter than CO_2. Hence, a reduction in CH_4 emissions would lead to a fairly rapid decline in total radiative forcing, if other greenhouse gas emissions could be stabilized (Cox and Jeffrey 2010). Finally, the manure from animals releases large amounts of nitrous oxide (N_2O) (McMichael et al. 2007), which, because of its long atmospheric lifetime, is about 300 times more powerful than CO_2 on a per-molecule basis.

Digastric animals evolved millions of years ago and thus have released CH_4 for millions of years. During most of this time, atmospheric CH_4 remained at a constant level, but the human-driven, increased population of farmed digastric animals has contributed to a new CH_4 'plateau,' to which other sources, such as gas drilling, also contribute. Rice paddies are now a major agricultural source of CH_4. Similarly, these animals have always produced manure and N_2O, but the volume is much larger now. Eventually, if land clearing were to cease, the CO_2 emissions associated with it would stabilize, and then decline, as recovering, growing forests would absorb more CO_2 than emitted by the clearing of forest.

Stabilization of these emissions does not seem likely in the near future, given the pressure to feed the relentlessly expanding human population, which is increasingly demanding diets high in meat. Humans are converting a reservoir of biodiversity and ecosystems that provide mainly regulating services into provisioning ecosystems that grow large quantities of grain, soy, and palm oil (Danielsen et al. 2008). This effectively places Earth in a regulating services deficit. Unless corrected, this will initiate a cascade of events leading to a future Earth that is less likely to provide a habitat conducive for human civilization. Additionally, this transformation, unless slowed, will be accompanied by the extinction of numerous species, including many that humans regard as charismatic.

1.05.5.4 Other Provisioning Ecosystem Services

1.05.5.4.1 Biofuels

Human reliance on ecosystems extends far beyond food. Already, more than 5% of the global grain yield (mostly corn) is used for biofuel, mainly ethanol, a liquid fuel from plants. Although ethanol has low 'net' energy, its production is justified because it can produce a liquid fuel that complements oil and can be used for transport. In the United States, about 40% of the annual maize crop is used for ethanol, although a small fraction of the plant's energy is recovered as brewer's grain and used as animal feed. The use of other food crops for biofuel is also increasing, including sugar cane and palm oil. Australia is contemplating allowing the large-scale harvesting of forests, trees of which will be burned in power stations to produce electricity.

Biofuels require soil, water, fertilizer, farm machinery, labor, and effort to plant, harvest, and process. Most currently used biofuels compete directly with food crops, thus elevating food prices, which are already near a record peak. In turn, increased food prices add markedly to the risk of famine, poverty, and other drivers of undernutrition (Rawe et al. 2012). Indirectly, these stresses contribute to other forms of human insecurity, including insurgency.

1.05.5.4.2 Medicinal Products

On the positive side, the potential of yet undiscovered plants with therapeutic value is a powerful motivator to conserve ecosystems (Chivian and Bernstein 2008). In reality, the loss of indigenous people and languages and the erosion of other forms of indigenous knowledge mean that the identification of such substances is increasingly handicapped. In addition, the alleged pharmacological benefits of natural substances, especially body parts of animals, including some species that are endangered, have caused enormous harm to ecosystems (Graham-Rowe 2011). Examples include the harvesting of bile from imprisoned bears in China and trophy hunting of Mongolia's Gobi bears (*Ursus arctos gobiensis*), a species critically threatened with extinction. Pressures of rising population and increasing poverty continue to motivate many people to exploit whatever they can to survive. Another form of ecosystem provisioning service is culturally valued plants and animal parts that are used for decorations and status symbols, such as certain feathers, paws, and shells.

1.05.5.5 Regulating Ecosystem Services and Infectious Diseases

In recent years, a body of literature has appeared that argues that plentiful biodiversity and ecosystems can regulate (limit) infectious diseases. In reality, the relationship is rarely this straightforward (Butler 2008; Randolph and Dobson 2012). However, there are many cases in which ecological changes have altered and continue to change infectious disease epidemiology. This usually occurs in combination with human and climatic factors, including exposure to nature and public health measures, such as vaccine status and the use of insecticide-impregnated bednets. Examples are numerous. They encompass many vectorborne diseases, including Lyme disease, malaria, dengue fever, Japanese encephalitis, and onchocerciasis.

In other cases, however, ecosystem transformation has led to health improvements, such as filling of swamps, which reduces mosquito populations. Areas of intensely preserved biodiversity may be reservoirs of infectious agents, from Ebola to HIV. Many developed countries led the world in modifying their habitats; they generally enjoy high life expectancies.

1.05.6 Conclusion

The significance of the relationship between ecosystems and human health cannot be overstated. Good health requires healthy ecosystems. Ecosystems, of which humans are a part, generally have the capacity to sustain their own health; biodiversity is essential to achieve this. However, human population size and ever-intensifying manipulation of the environment have degraded most ecosystems, some to a critical level and others to collapse.

There is widespread denial about the extent, trend, and consequences of the relentless transformation of 'natural' ecosystems. Many highly transformed ecosystems risk critical degradation because of overuse, overgrazing, and contamination by chemicals, invasive species, and even landmines.

We conclude by discussing some of the factors required to emerge from the great danger that now confronts humanity and many other forms of life. To reduce the negative effects of climate change and fossil fuel depletion (Murray and King 2012), a range of technological strategies are emerging, although it is far from certain that these can be implemented at the required rate (Smil 2011). Slowing and reversing greenhouse gas accumulation is essential for human well-being, but far more than this is needed, and urgently so, too.

A range of nascent strategies exist for protecting some ecosystems. These include treaties and other international agreements to protect wild places (Antarctica, the Arctic, national parks) and wild species (charismatic animals). Other mechanisms include exchanges of 'debt for nature' (which seek to preserve large ecosystems) and legal agreements to offset carbon emissions in rich countries by protecting forests in developing countries, and in so doing, preserve biodiversity. To date, however, all such agreements share an ominous fragility. Even the ultimate protection of Antarctica must be considered at risk, especially to mining. The Arctic is also ripening for a mining and shipping boom, regardless of further damage to its ecosystems and to the global climate (see 4.39, Vulnerability and Adaptation in the Arctic).

Although more people and societies are awakening to the harms from ecosystem degradation, a decline in human well-being and the health of present and future generations appears inevitable if these trends continue. Although some Tragedies of the Commons (Hardin 1968) have been averted by regulation and cooperation (Buck 1985), this cannot be relied on, given the breadth and scale of current trends that lead to complacency. Many aspects of the global commons are worsening every year, and this deterioration seems likely to continue. Its prevention requires a vast amount of effort, exceeding that of the Space Race or World War II (Hoffert 2011).

Many barriers impede our collective capacity to change course. These include denial, the human capacity for adaptation, and recent apparent successes at extending human 'carrying capacity' (Butler 2004). A major cause for the erosion and loss of the many ecosystem services discussed at the start of this chapter is the displacement of most of the apparent harms and risks to a fraction of the global population that is far removed, conceptually and experientially, from those with more political and economic power. In this sense, the increasing destruction of the natural capital embodied in ecosystems is reminiscent of the destruction of English, Scottish, and Irish yeomen by the establishment of industrialization in nineteenth-century Britain. The Industrial Revolution generated unprecedented material abundance, but until social reform, it lowered the living standards and life expectancy of most of the British population (Szreter and Mooney 1998). The twenty-first century's ongoing loss of biodiversity and ecosystem services similarly threatens human well-being. Such effects are very unevenly distributed.

Several decades after its nadir in the early nineteenth century, life expectancy in Britain recovered (Szreter and Mooney 1998). Globally, life expectancy has not yet started to decline, although its rate of increase has unexpectedly slowed. The remainder of the twenty-first century is likely to determine our fate. A 'muddle-through' world could evolve, assisted by new price signals and energy technologies and a greater recognition of our indigenous nature (Butler 2010b) (see 4.35, Scenario Planning for the Future). That future may see improved well-being; if so, humanity will have learned not only that planetary resources are limited but also that other species and ecosystems warrant an enduring habitat on Earth.

1.06.1 Introduction

The topic of human health ranks high among societal concerns (Cohen and Martinez 2010). In 2005, the United States spent $95 billion on medical research, with studies showing that Americans want more funds and resources devoted to health care and research (WHO 2009). Deteriorating environmental conditions are a major contributor to poor health and reduced quality of life, directly responsible for 25% of all preventable illnesses, specifically diarrheal and acute respiratory infections (DeNavas-Walt et al. 2010). According to a recent report by the World Health Organization (WHO), approximately 7% of deaths and diseases around the world occur because of inadequate or unsafe water, sanitation, and hygiene, and an estimated 5% of deaths and diseases are due to air pollution (WHO 2009). Extreme climatic events, such as floods, earthquakes, and droughts, also increase the risk of diarrheal disease and outbreaks of vector-borne diseases. Such extreme events threaten not only the individual's health but also access to health care. In Pakistan, for example, more than 200 health facilities were destroyed or damaged by the flood of historical proportion during the summer of 2010 (Stedman 2010). The aftermath of the Pakistan's flooding includes the rise of communicable diseases – acute respiratory infections, diarrhea, and skin infections, as well as cases of malaria – prompting the need to develop a larger adaptive capacity as well as strengthening the current public health response.

Where increases in temperature and precipitation have occurred, they have contributed to an increase in vector-borne diseases, particularly dengue fever. The incidence of dengue increased 30-fold since the 1960s, spreading in geographic scope and from urban to rural communities where health care may be less accessible (Fouillet et al. 2007). In addition to higher average temperatures, the number and intensity of heat waves could increase as a result of variability and change in weather patterns. The 2003 summer heat wave in Europe showed how the rich and poor worlds are equally vulnerable to nature. Those with a weak adaptive capacity were at risk, such as the population subgroup with respiratory and cardiovascular disorders and the elderly children.

The effect of extreme climatic conditions cannot be minimized (Trenberth et al. 2000). Extreme weather events include precipitation extremes, severe storms, heat waves, and flooding and have caused many deaths and injuries each year in the United States and around the world. Changes in weather patterns would alter the timing, frequency, length, and intensity of extreme events (Greenough et al. 2001). Increases in heavy precipitation have been reported over the past century (IPCC 2007). The severity of such changes is also related to the reliability of one's health care infrastructure to support such events, as well as its accessibility. For example, in Pakistan, approximately15 million people were affected during the flood of 2010. Again, clean water and sanitation were scarce. Many millions needed health care assistance, especially those affected by communicable diseases such as malaria; however, owing to the flood waters more than 200 hospitals and clinics were damaged or destroyed, limiting access to health services. Weather patterns play a key role in influencing natural ecosystems as well as the human systems that are dependent on them. Because many entities are tied to climate, any variability in climate has far-reaching effects, such as human and animal migration patterns, food production, water availability and use, and health risks. Warmer average temperatures combined with increased variability would alter the pattern of exposure to thermal extremes and resultant health impacts in both summer and winter (WHO 2009). According to the WHO, in developing countries, approximately 2.4% of diarrhea and 6% of malaria cases are caused as a result of water contamination during time of floods.

In the following section, the authors review the salient research that outlines the concept of and factors that contribute to society vulnerability. This section also reveals the concerns surrounding vulnerability and climate variability and long-term change and its impacts on human health. In Section 1.06.3, the authors detail the implication of climate in human health. Just as it is imperative to understand the impact of climate in health outcomes, it is also vital to discuss the role of public health systems in reducing social vulnerability to climate. Likewise, it is also important to discuss how vulnerable regions and society provide a focus of new research, resulting in additional knowledge that is relevant to the needs of society with different social, cultural, and environmental conditions. Sections 1.06.4–1.06.6 will show the complexities involved in the analyses of climate and its effects. After a brief discussion of methods, the authors explore the literature on the human health consequences, both indirect and direct, as a result of climate, and how the issues surrounding climate are complex and dynamic. In the final section, the authors justify the rationale for different levels of thinking and planning that are required for improving the social consequences of climate.

1.06.2 Social Vulnerability to Climate and Other Ongoing Changes

Vulnerability, within the context of health, can be expressed as one's susceptibility to shocks emanating from climate and other factors. Vulnerable populations include those at risk of poor physical, social, and/or psychological health, and there are groups of people who have a higher probability of becoming ill (Shi and Stevens 2005). There are a variety of determinants of vulnerability, including homelessness, poverty, disability, chronic illness, age, gender, social status, low income, and lack of education. The effects on human health from these events include physical injury, increased exposure to disease pathogens and/or their vectors, exposure to airborne allergens and chemical releases, nutritional deficiencies caused by food shortages, and psychosocial and mental health outcomes associated with loss, disruption, and displacement. Those in low-income countries may be more susceptible to heightened exposure to infectious disease (endemic waterborne, insect-borne, rodent-borne, and food-borne diseases) because of compromised water and sanitation systems (Cutter 2006). Environmental variability at various levels can result in intensifying vulnerability to the health impacts. These environmental changes alter the probability of human exposure to hazards as well as people's susceptibility to their impacts (Few 2006). A major concern is the impact that extreme events could have on health care systems. Without the institutions and services whose role is to protect and help maintain health, a society's ability to recover would be greatly hindered. People who are poor and lacking in education may wait too long and have less access to health care. Those with little or no income may not have the time or financial stability for preventative health measures (Adger 2006). Floods and windstorms can damage these institutions during times when they are needed the most.

Impacts on society are not just shaped by physical forces alone. For example, during and following a flash flood, the consequences can range from direct physical injuries to psychosocial effects of sustained exposure to flooding events (Few 2006). Hazards much like flash floods can have an interactive effect on health, for example, the links between inadequate nutrition and disease susceptibility, and mental health and indisposition (Shi 1997). Many of the events discussed within the literature include floods, windstorms, wildfires, and droughts. Extensive fires in forest areas have the possibility of causing and exacerbating respiratory problems worldwide. Increased drought can result in the worsening of the effects of malnutrition and risk of disease in Africa (Few 2006). The vectors of disease-causing organisms may shift to other locations as a result of rising temperature. There are a multitude of factors that may intensify vulnerability to the health impacts of environmental hazards. If, for example, surface vegetation changes are substantial, the potential for drought and loss of mangroves in coastal areas increases; this may lead to a loss of natural protection against waves during storms (Few 2006). Vulnerability can be considered a combination of social factors and physical factors. The former deals with a population's susceptibility to impacts, whereas the latter refers to the probability of physical exposure to the event.

Social vulnerability varies depending on the behavior of and the resources available to the population (Few 2006). The concept of 'coping capacity' is intertwined with social vulnerability; how well can people avoid infection and how robust is the health care infrastructure to continue running during an extreme event? In addition, vulnerability includes two factors, 'external' and 'personal.' What is the person's current health status, mental health status, and nutritional health status? These aspects can influence an individual's vulnerability to illness. Each person has characteristics, either inborn or acquired, that interact with the environment and influences health (Rogers 1997). According to Rogers (1997) these characteristics may include temperament, genetic predisposition to disease, drug sensitivity, and susceptibility to illness. Acquired characteristics may include life experiences and learned abilities such as coping skills. These factors may affect the individual in his/her response to stress events. External components of vulnerability include a person's immediate environment as well as the individual's family and community. It is important to note that the full scope of health impacts and the complexity associated with them extend beyond those mentioned in this chapter. The following paragraphs discuss the vulnerability associated with population and climate.

1.06.3 Climate and Human Health

Although early discussion on climate effects and human health mostly focused on heat stress, infectious disease, and extreme weather events in specific regions, recent studies are beginning to evaluate the social, economic, and demographic factors in relation to health risks. The evolving discussion on climate and human health can be seen in two overlapping but distinct phases. The first phase, where the more early literature is placed, is characterized by the limited scientific literature on health impacts as a result of climate. Predictions that vector-borne diseases such as malaria could spread to other locations as a result of changes in weather patterns were a significant part of the discussion within the early research (Ropelewski and Halpert 1986). The idea that water quality could be potentially affected as a result of heavy rainfall, leading to contamination, was also addressed (Cook 1992). Increases in temperatures were reported to likely change the prevalence or intensity of asthma and allergic disorders (Hulme 2009). On a lesser scale, psychological disorders such as depression and anxiety have been hypothesized to increase. Increases in climate variability may alter temperature and rainfall patterns, disrupting practice of agriculture and supply of water resources, leading to malnutrition especially in vulnerable populations (Confalonieri and Menne 2007). Because of the limited scientific research available during the first phase, the effects on human health are reported as 'likely' or 'possible' to occur. While scholars continue to unravel the link between illnesses and seasonal trends in temperature and rainfall (Persinger 1980), much of the research in this phase concentrated on heat- and cold-wave episodes.

Within the second phase, characterized by the increased confidence of the effects of climate on health, focus shifts to the role of public health and adaptation responses in these later articles (Fouillet et al. 2007). For example, climate has been found to be a more important determinant of life expectancy in African countries (developing) than in non-African countries. While climate is important in determining both life expectancy and income, the latter can also play a part in tempering the negative impacts of climate on life expectancy (Schar 2004). This is to say that climate conditions that lead to warmer temperatures and drought and floods may lead to developing countries remaining trapped in underdevelopment of health (Kovats et al. 2003). The role of public health and climate has become an important part of discussion to date, whereby vulnerable regions provide a focus of new research, resulting in additional literature. Along with revealing the complex interactions behind climate and human health, adaptation methods are also being developed to lessen the effects of climate on health.

1.06.4 Water and Human Health

More than a billion people live without access to freshwater. Water can be seen as an indicator of health, as it is clear that without access to potable water survival chances are lowered. Half of the world's people are living in areas where water tables are falling, including China, India, and the United States, who are the biggest producers of grain (Brown 2008). Water scarcity is reported to affect one in three people in the world. Population growth, urbanization, increases in industrial and household uses exacerbates the problem. Along with quantity, quality of water is equally important. A variety of different microorganisms can affect the quality of a water supply. The most common microbes found in water are bacteria, protozoa, viruses, and helminthes. Some of these pathogens may be found naturally in the water supply, and others may be introduced into the supply through human and animal waste contamination (McMichael et al. 2003). Bacteria can be found naturally in both groundwater and surface water. Pathogenic bacteria found in water supplies generally come from human and animal waste (Arnell et al. 1999). Protozoa are found usually in oceans, rivers, lakes, ponds, and other aquatic habitats. Protozoa have the capability of making their way into groundwater from the connection between an aquifer and surface-water source through compromised wells or springs (Kovats et al. 1999).

Inadequate safe drinking water and a poor health care infrastructure, as well as lack of access to health care providers, as in the aftermath of the Haiti earthquake in 2010, can put human health at risk. Cholera, as with many other infectious diseases, is transmitted primarily through consuming contaminated drinking water or food. An outbreak of cholera followed the devastating earthquake in January 2011. The outbreak began in October 2010, and by March 2011, approximately 4672 people died (Walton and Ivers 2011). Cholera had spread to all of Haiti's 10 provinces by the first week of the epidemic. Since then, cholera has spread to some of the neighboring countries, including the Dominican Republic and Venezuela. Because many of Haiti's residents are unfamiliar with cholera, and without a strong public health system, there are many misconceptions about the disease. According to Doctors Without Borders (2011), for example, some may choose to stay away from the treatment centers for fear of having the centers in their neighborhood because they believe it helps to spread the disease; however, the opposite is true, it is more beneficial to one's health to have a treatment center close to the population. The importance of a proper health care center is a key factor; cholera treatment centers must allow for patient isolation to ensure effective treatment. In the United States, *Vibrio vulnificus* infections were identified by health officials in evacuees from New Orleans as a result of the flooding from Hurricane Katrina (Bopp et al. 2005).

Many pathogenic viruses and helminthes, like pathogenic bacteria, are introduced to water supplies from human and animal waste contamination as well (Arnell 1999). Symptoms vary and can include cramping, vomiting, diarrhea, fever, dehydration, abdominal pain, chills, nausea, fever, coma, loss of appetite, severe weight loss, fatigue, jaundice, dysenteric or urinary symptoms, itching on skin and dermatitis. Heavy rainfall events are one consequence of climate variability, which directly impacts water availability and quality. Literature shows an increase in the number of outbreaks of waterborne diseases as heavy rainfall events increase, suggesting a scientific consensus that the progression of climate variability has an overall negative impact on water quality (Bilham 2010).

1.06.5 Human Health, Food, and Nutrition

Higher temperatures (within a range) increase replication cycles of food-borne pathogens (Rose et al. 2001). Food-handling mistakes may be more prevalent in prolonged seasons. In the United States, these diseases cause approximately 76 million cases of illnesses, with 5000 deaths per year (Newell et al. 2010). As a public health issue, a large number of food-borne illnesses are reported and are associated with economic costs. Pathogens like salmonella multiply at room temperature. The WHO Surveillance Program for Control of Foodborne Infections and Intoxications in Europe indicate that 32.5% of outbreaks are a result of time–temperature abuse. A study done in Australia reported an association between increases in salmonellosis infections and increased temperature (Tirado and Schmidt 2001).

Climatic factors, particularly precipitation and temperature, are closely related to food-borne illness. Those who rely on marine-based diets may be at a greater risk, as weather variability has been associated with coastal water contamination and shellfish-related diseases (Miraglia et al. 2009). *Vibrio* spp., and the diseases caused by the species, is strongly manipulated by climate factors, especially temperature. In more subtropical regions, this pathogen thrives. Salinity also plays a large role in its survival. Another example of how weather has the potential to influence food-borne diseases is through the transmission of *Cyclospora cayetanensis*, which causes diarrheal disease (Newell et al. 2010). The growth cycle and maturation of this protozoan consists of a process called sporulation, which is dependent on warm temperatures. Studies have shown that this protozoan has a distinct seasonality that peaks in the summer months (Miraglia et al. 2009).

Crop pests such as locusts, aphids, and whiteflies can thrive in dry environments and can spread a mold that makes aflatoxin, a substance that may aid the development of liver cancer in those that ingest contaminated corn and nuts (Rose et al. 2009). Researchers believe that climate variability and change may ravage crops that are already stressed, which would worsen malnutrition and poverty and fuel human migration. If agricultural pests and weeds spread, and there is increased use of toxic pesticides, farm workers and their families could be harmed (Newell et al. 2010). Agricultural crops and fisheries may be compromised as a result of runoff and toxic spills released into the environment from extreme weather events due to climate variability and change (Newell et al. 2010).

1.06.6 Heat Waves

Heat can be a natural hazard. High temperatures can bring about symptoms of heat stroke, heat exhaustion, heat syncope, and heat cramps (Kovats 2008). Severe heat stroke is defined as core body temperature exceeding 103 °F and dysfunction of multiple organs. The progression to death from heat stroke can be a matter of hours, while survivors may have permanent damage to organ systems. Although the phrase ‘heat wave’ does not have a universal definition, they are considered extreme events that are associated with continuous, hot temperatures that can be fatal to humans (Meehl 2004). Examples include the 1995 Chicago heat wave, the European heat wave in 2003, and more recently the Australian heat wave. In each instance, human health and well-being suffered. From past heat wave events, health risks have become evident. In the case of Chicago, more than 500 heat-related deaths were reported. As all heat waves are considered preventable, the lack of preparedness was evident. In the European heat wave of 2003, more than 30 000 excess deaths were reported, with approximately 2000 deaths occurring in Paris. Because the heat wave occurred during the holiday season, the heat stress was exacerbated by the lack of hospital staff.

The heat wave that Russia experienced during the summer of 2010 is an example of potential impacts of climate on human health. The heat wave killed approximately 11 000 people in the city of Moscow, helped spread wildfires, and took out more than one-third of the country’s grain harvest, which drove up food prices globally. Climatologists in Russia noted that no similar event had been recorded in at least a thousand years; however, more recent studies disagree that it was so unprecedented (Dole et al. 2011). The extreme temperatures were due to a major high-pressure ridge that stopped the normal movement of cooling storms that come from the west, which allowed warm air to flow north from the tropics. These anomalies are common and result from natural instances; however, the intensity of the occurrence over Russia was unusually strong. Because of the complexities behind the science of blocking events, more research is needed to determine the role of climate variability and change in these events.

In 2009, many regions in Australia reached record temperature highs. The heat wave exacerbated fire conditions during the 2008–09 Australian bushfire season, causing many bushfires in the affected region and leading to the Black Saturday bushfires, which killed 173 people in Victoria (Nitschke et al. 2011). Many people, a majority being elderly, were treated for heat-related illnesses. In addition, many homes and businesses lost power for days. Railway lines were stopped, and many acres were destroyed. The state’s power supply also collapsed as many residents tried to use air conditioning. In a matter of barely 3 days, Hurricane Mitch in 1998 brought some 6 feet of rain on Central America. In the ensuing days, the incidence of malaria, dengue fever, cholera, and leptospirosis soared (Epstein 2005). In Mozambique, three cyclones inundated the country for 6 weeks in 2000, whereby the incidence of malaria rose fivefold. These cases are clear indicators stressing the need for a strong response and recovery unit within a working public health system (Nitschke et al. 2011).

While many heatstrokes result from activity in hot weather (e.g., working outdoors, playing sports), in the case of individuals who are less fit, these heat illnesses can occur even when performing low levels of activity. This is due to the low cardiovascular reserve associated with lack of exercise, which leads to low heat tolerance. There is a clear limit to which the human body can tolerate heat. From studies done in Saudi Arabia, evidence has shown that after a severe heat wave, heat stress proteins were created and reactions of the immune system were significant in causing deaths (Bouchama 2002). Humans do have the capacity to adapt to changing climates and environments. We have seen differences among cultures in physiological, architectural, and behavioral aspects because of differences in climate. People who live in warmer climates have been shown to have higher thresholds to hot weather, in terms of adaptability. Examples of this include those who have moved to hotter countries, including soldiers and athletes. This physiological adaptation takes place over a few days to weeks. The body’s response is to increase the number of sweat glands and improve cardiovascular stability to heat exposure. Behavioral changes also play a part, including clothing, diet, activity, and drinking (McGeehin 2001). Heat waves occur in all countries; however, some countries are more vulnerable than others. The two main reported groups of people at highest risk are young children and the elderly. It is the changes in the thermoregulatory system that makes elderly people more vulnerable to heat (Meehl 2004). Children and babies also have a higher risk of dehydration and lower thermoregulation capabilities.

1.06.7 Vector-Borne Disease

The relationship between climate and infectious diseases has been studied for centuries. In his 1840 treatise *On Miasmata and Contagia*, Jacob Henle stated, "Heat and moisture favor the production and propagation of the infusoria and the molds, as well as the miasmata and contagia, therefore miasmatic-contagious diseases are most often endemic in warm moist regions and epidemic in wet summer months." He noted cholera and yellow fever among the miasmatic-contagious diseases, and today, as global warming continues, these diseases may resurge. There are three different components working together: the vertebrate host, the invertebrate vector, and the parasite (bacteria, viruses, etc.). Each part is responsive to environmental changes in different ways (Patz and Reisen 2001). Increased temperatures generally speed up the development of both vectors and pathogens and can lead vectors to bite more often (increasing transmission rates), but higher temperatures, above a respective threshold, can cause higher vector deaths (lowered transmission rates). In the highlands of Africa, cool temperatures limit malaria parasite development; if temperature continues to increase, malaria transmission may increase as well (Githeko et al. 2000). In addition, St. Louis encephalitis viral replication and length of transmission season are dependent on temperature; 'snowbirds,' the migratory, nonimmune elderly population of southwest United States, would be at higher risk if they arrive in early fall to stay for the winter months (CDC 2011a). Also, dengue fever transmission season may be prolonged if aided by warmer temperatures (CDC 2011b).

1.06.8 Methods

For the purpose of this chapter, the authors applied bibliometric analysis to understand the trends in climate variability and human health discourse. Following Neff and Corley (2009), coword analysis was applied (i.e., words most commonly used together in titles, abstracts, or list of keywords). The theory of coword analysis is taken from the idea that research areas can be characterized and analyzed from patterns of keyword use in publications. When new concepts and ideas are put forward or the community accepts new methods, the keywords that stand for the concepts allow for subsequent authors to build upon the idea (Neff and Corley 2009). For the scientific literature, relevant reports and publications were identified from electronic reference database using combinations of keywords of 'climate change' and 'health.' Climate change, although a nebulous construct, was used since this is the phrase most commonly used when referring to climate variability.

When examining specific topics within climate variability and health, a combination of keywords were used that were developed from the health outcome categories, limited by date. The following databases were searched: Medline, BIOSIS, Web of Science, and CSA Illumina social sciences index. Results of individual searchers were filtered using a series of Boolean pairings. In each of the database searches the option for full document was searched for the keywords. Only English articles and publications that appeared to provide information on the impacts of climate on health were analyzed.

If the abstract suggested that a publication might provide useful information, or the title or keywords supported such a conclusion when an abstract was unavailable, the publication was obtained and reviewed. When examining the discussion of the role of physicians in climate and health, the following medical journals were analyzed: *British Medical Journal, Journal of the American Medical Association, The Lancet, and New England Journal of Medicine*. Google Scholar was used to search within the specific journals. Duplicates were filtered out using RefWorks, which identifies duplicates and allows the user to delete unwanted articles. In analyzing the news media, the Proquest historical newspaper database was used to search the New York Times as well as Google News. For both, the earliest relevant articles began in 1985. In addition to overall content, front-page stories were also examined.

1.06.9 Results and Discussion

1.06.9.1 Surge of Publication: Bibliometric Analysis

Understanding the effects of climate variability and change and preparing for future events is important for public policy in health. In turn, a strong public policy is necessary to ensure safety. The summer of 2003 was reported to be the hottest in Europe since, at the latest, AD 1500 (Stott et al. 2004), although Chase et al. (2006, 2008) and Connolley (2008) show that, in the global context, such extreme heat waves are not unusual. This resulted in unusually large numbers of heat-related deaths in several countries in Europe. A French parliamentary inquiry stated that the health impact of this event was unforeseen. In addition, this event revealed weaknesses in the surveillance for heat wave deaths, the lack of knowledge leading to an inadequate public health response, and the limited strength of public health agencies as well as the lack of communication between public organizations (Fouillet et al. 2007). Following this heat wave event, the literature increased substantially (**Figure 1**). The content consisted of determining the cause of the heat wave to be in some part due to anthropogenic climate change, as well as discussing ways to prevent deaths and injury if and when similar events occurred and ways to fix the weak points in the public health system. Similar outcomes have been seen for other extreme events such as Hurricane Katrina, which revealed the shortcomings of the Federal Emergency Management Agency (FEMA) (Brodie et al. 2007).

1.06.9.2 Absence of Physicians in the Discussion of Climate and Health

Although there is a call for the participation of physicians, there is notable absence of them in the debate of climate and health. A physician's opinions can have credence to the general public as has been reported by Sarfaty and Abouzaid (2009), who found that physicians are the most trusted source for health information. This could help build public consensus that is needed at a time when climate variability and change has become a political polarized issue (Mitchell et al. 2002). The role of the doctor has yet to be clearly defined within the climate and health discussion. The literature presents multiple ways in which physicians could potentially address the nexus

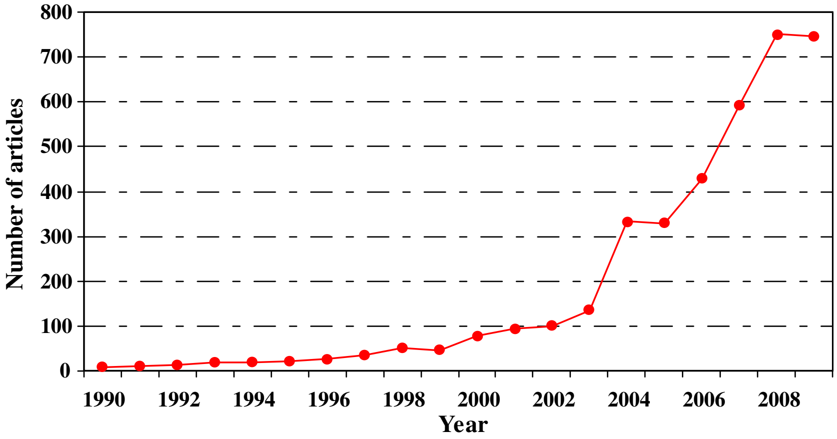

Figure 1 The number of articles from 1990 to 2009 discussing climate variability and heat waves. The circled point indicates when the 2003 European heat wave occurred.

between human health and climate (Sarfaty and Abouzaid 2009). In clinical medicine, climate variability and other environmental stressors are already causing patients in particular regions, certain ages, or with certain medical conditions to seek clinical care. In addition to clinical medicine, reducing carbon emissions in the workplace, using communication outlets to educate patients and the public, using surveillance means to identify conditions related to or caused by climate, and public policy are other contexts in which physicians can get involved (Sarfaty and Abouzaid 2009). As experts in their field, physicians are often called upon to impart health knowledge to aid the public.

1.06.9.3 News Media, Health, and Climate Variability and Change

Americans still think mostly about ice caps and polar bears when climate variability and change is mentioned (Sarfaty and Abouzaid 2009). The number of 'climate skeptics' is greater in the United States than in any other country. Scientists and lay public differ sharply about their views on climate variability and its causes. A Pew Research Center (2009) poll found that 84% of scientists believe that the Earth is getting warmer because of burning of fossil fuels, whereas just 49% of the US public held this view. Several factors may be contributing to this difference in the understanding of climate variability, with media being the important one. For most lay people around the world, and certainly in the United States, exposure to climate science has been almost entirely from general media and not from climate scientists (Weber and Stern 2011). Media reporting, as we all know, follows rules different from those of scientific reporting, whereby maximizing audience share and conforming the value of the media outlet's owner is the primary goal of the media (Hulme 2009). Even though there is a general consensus of anthropogenic influence, media depictions often are too dramatic and dividing and are more pervasive in the United States. It is primarily through the media that climate variability is represented publicly (Carvalho 2007; Weber and Stern 2011). Scientific knowledge is also used by other entities, including activists and businesses, to justify certain actions or campaigns. Thus, as new pathways between the citizens, politicians, media, and scientists are established, the ties between science and politics have gone public and therefore welcome more criticism and evaluation (Boykoff 2007).

Although there is a general consensus, there are still many aspects within climate variability (and especially within climate variability and health) that are labeled 'uncertain' because of the complexities involved and additional studies required. This

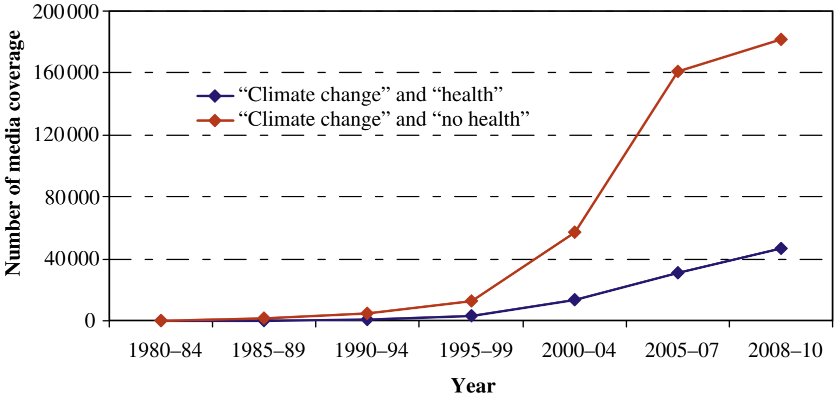

Figure 2 Articles discussing climate variability and health versus climate variability and topics other than health.

'uncertainty' becomes an issue in journalism; in many reporting situations, journalists avoid abstract storytelling (Weingart et al. 2000). This may lead to the climate variability dimension aspect being cut out of a story, if it is too uncertain. On the other hand, journalists may narrow their focus regarding climate variability-related issues, depending on what they see as 'the story.' For example, the story may be found in the visual nature of a flood and other extreme weather events or may be politically relevant, resulting in losing the long-term picture of the bigger issues (Boykoff 2007). While Americans rank climate variability and change as a low-priority issue, it is interesting to note that climate risk perceptions, behavioral intentions, and policy priorities shifted significantly following the release of *The Day After Tomorrow* (Leiserowitz 2004).

In terms of climate and human health, it appears that the majority of the discussion is not directly health related but stems from elsewhere (mostly an integration of politics of climate change) (Figure 2). For example, in President Obama's new vision of a US energy economy, "[We can] pass comprehensive energy and climate legislation that will ignite new industries, spark new jobs in town like this [Iowa] and make America more energy independent" (Leiserowitz 2004). In general, although human health is generating some discussion within climate-related news, an overwhelming majority belongs to topics other than health-related issues.

1.06.10 Conclusions

In tracing the information presented in the academic literature, the implications of climate variability and long-term change are significant for human health, which in turn calls on public health action. This chapter concludes that the discussion on human health and climate has evolved and the human health link established. The topics of water- and food-borne diseases within the nexus of climate and human health discussion are two examples of how altering the physical environment can lead to a range of human health effects through water stress and waterborne diseases; water management and policy are also affected. In the discussion on human health and climate, there seems to be a handful of authoritative figures that the public and politicians can turn to for information, physicians and the public health sector, the news media, and the scientists. In order to be most effective, it may be necessary for the interdisciplinary dialog to be strengthened between these three sectors. Although new pathways to the same health risks through climate variability and change are being highlighted, the message has stayed consistent since the beginning; inadequate action has been taken even with the increase in knowledge of the effects of climate variability and change. One possible action may be, once an interdisciplinary team is formed, to start within the United States and to inform and train other officials and health professionals about the health risks from the effects of climate variability and change. This model may then be taken to other countries that are more vulnerable to start a similar interdisciplinary sector. However, it may be more difficult to start within the United States, as the population has not had much interaction with health and climate interaction, versus within a region where the effects are clearly evident and where the population is more apt for action.

1.07.1 Introduction

The aims of this chapter are to describe the threats and risks to human health related to the impacts on food and nutrition, of environmental factors including those consistent with climate change and to demonstrate that global and regional strategies will be needed if adaptation and mitigation measures to reduce negative health impacts are to be effective, especially in developing countries, where the burden of ill health is already high. The climate factors that influence food and nutrition directly are heat waves, extreme weather events such as floods, sustained daytime and nighttime temperature rises, increased precipitation, and drought. Indirect impacts are also likely from changes in agrosystems and hydrology and disruptions of natural ecosystems and their effects on plant pests and disease (World Resources Institute 1998-1999), as well as socioeconomic and demographic factors attributable to climate.

1.07.2 Malnutrition

Epidemiological studies have shown that deficient intakes of energy, protein, or micronutrients are associated with ill health and increased mortality (Van den Broek 1995). The relationships between food insecurity, malnutrition, morbidity, and mortality are well documented (Young and Jaspars 2009). A major study stated: "Multiple biological and social factors affect the incidence of malnutrition but one of the fundamental determinants is the availability of staple foods. Climate variability may affect this…" (McMichael et al. 2004). However, malnutrition has its biggest impacts in populations where mortality levels are already high. It is already obvious that food insecurity and poor nutrition are distributed unequally between regions and countries. For example, a 2009 report showed that in India, 37.4% of females and 39.4% of males suffered from chronic energy deficiency, with undernutrition most serious among rural and the most deprived populations (Government of India Ministry of Environment and Forests 2009).

Immunologic defenses are impaired in malnutrition, and hence, infections tend to last longer and are more likely to lead to complications. Severe anemia and severe bronchopneumonia resulting from malnutrition are frequent causes of death in children in some developing countries. In countries where temperatures fall drastically at night, malnourished people risk death from hypothermia. These effects tend to be worse among the most deprived populations, and more so among girls, as they are compromised by poor access to health care, lack of education, and preferential concern for the health of male children (Van den Broek 1995).

The relation between malnutrition and mortality is exponential – in a worsening nutritional crisis, malnutrition and mortality increase in a curve that becomes steeper (Young and Jaspars 2009). Food insecurity is also associated in developing countries with stunting of children 0–24 months, while severe stunting is associated with a longer term mortality risk in the same age group. Stunting is associated with greater child mortality and also has medium and long-term impacts such as cognitive impairment, poor school performance, decreased work capacity, and increased risk of adult morbidity and early death (Young and Jaspars 2009). The effects of undernutrition are considered to span at least three generations. The prevention of stunting requires population-wide interventions, preferably before conception. Malnutrition also contributes to a range of diseases: underweight is documented as an underlying cause of child deaths associated with diarrhea, pneumonia, malaria, and measles (Young and Jaspars 2009). Also, most child deaths in developing countries result from disease made worse or aggravated by malnutrition.

http://dx.doi.org/10.1016/B978-0-12-384703-4.00114-3

Despite significant achievements during the past century, gender inequalities continue to shape the daily lives of many women worldwide and put them at greatly increased risk of adverse health impacts due not only to climate variability (Blomstrom et al. 2009) but also the prospect of longer term climate change. Women are the main producers of food especially in the developing countries, and yet own less than 15% of land (UNFPA 2009). When financial assistance or investment is available for agriculture in developing countries, women farmers tend to receive only a small a fraction of it (Chen et al. 1981), so that they are likely to be more disadvantaged in recovering from the adverse effects of climate variability. Women and girls in developing countries are also more likely to be malnourished than men and boys, since male household members generally consume more calories and proteins and may receive better health care than females, at all ages. Women and girls also have the biggest decreases in food consumption in the aftermath of climatic disasters including drought (Sivakumar and Kerbart 2004; Oxfam International 2005).

1.07.3 The Impacts of Social, Environmental, and Economic Determinants on Food, Nutrition, and Public Health

The proportion of people, worldwide, reported as hungry (i.e., with insufficient intake of food energy) by the Food and Agriculture Organization (FAO) plateaued at about 16% between 2000 and 2007, before rising. This trend, set against the context of the global economic crisis and rising food prices, has led to the conclusion that the Millennium Development Goal to halve, between 1990 and 2015, the proportion of people who suffer from hunger may be difficult to meet in many regions of the developing world (United Nations 2011), where an interplay of environmental, economic, and social factors expose the population to the risks of poverty and malnutrition (Lipton 2001). Several manifestations of local and regional climatic change would exacerbate these risks (Warren et al. 2006), especially in communities with higher levels of vulnerability and low adaptive capacity, and need to be considered within a common and integrated framework of environmental determinants of health.

Conventional assessments of risks to human health have focused on hazards whose magnitude can be measured and on determining dose–response relationships between levels of exposure and impact on human health (Patz and Balbus 1996). However, the health impacts of climate effects on food and nutrition are mediated through a complex spectrum of ecological and social variables, including the underlying socioeconomic and demographic vulnerability of the population. This requires the development of integrated models of risk assessments. This also necessitates the development of flexible adaptation strategies at regional and community levels, with governments, industries, and communities working together to monitor changes and establish support systems to improve the coping capacity of populations. These should help food growers adapt to a range of possible climatic scenarios and help the most vulnerable populations avoid the worst effects of food and nutrition problems. However, as this chapter explores, the impacts of climate occur within powerful global economic and trade systems. The regions where the largest negative health impacts are likely to occur are those most constrained by poverty and lack of power and development, and are thus least able to adapt. The climate effect on developing countries' crops and aquaculture occur within social, economic, and environmental factors that are often dictated by economic, trade, and aid policies and conditions outside their influence. Hence mitigation of the largest negative impacts of climate change on food, nutrition, and public health has to be addressed globally as well as at regional, state, and community levels.

1.07.4 Food Security

Food security occurs when all people, at all times, have physical, social, and economic access to sufficient, safe, and nutritious food that meets their dietary needs and food preferences for an active healthy life (FAO 2008). Agriculture and fishing produce the world's food supplies. Changes in temperature and rainfall and extreme weather events (Antwi-Agyei et al. 2012) would likely have significant impacts on agriculture and on fish stocks via sea temperature change. Hence, these changes can impact on food security, which is inextricably linked to nutrition and health as well as economic development, environmental sustainability, and trade.

Many countries lack food security, and the food and nutrition needs of most of their populations are precarious. The International Fund for Agricultural Development (IFAD) (2002) estimated that the basic daily needs for sufficient food of 1.2 billion people around the world are not met. About 800 million of them live on marginal land in rural areas and depend on rain-fed agriculture that is susceptible to disruption from climate (Ludi 2009). In developing countries, the pressure from rural poverty – increasing numbers of people trying to make a living out of decreasing resources – poses a major challenge to the agricultural sustainability needed to build food security (Alexandratos 1995; Lipton 2001).

The United Nations (UN) FAO defines four dimensions of food supplies: availability, stability, access, and utilization. Climate affects availability, since drought and increased average temperatures regularly wipe out crops in developing countries, causing famines. 'Stability' refers to people's risks of temporarily or permanently losing their access to food, through loss of the means to pay for it, for example (Schmidhuber and Tubiello 2007). Stability for the most disadvantaged populations can be directly affected by climate; for example, landless agricultural laborers who depend on agricultural wages in a region of erratic rainfall and have few savings would be at high risk of losing their access to food even though it might be available, if a drought wipes out crops and puts them out of work (Schmidhuber and Tubiello 2007). This same climate effect can also impact indirectly on others, when the subsequent migration of these rural populations to the cities adds to existing competition for incomes (and hence food) among the urban poor (Rao et al. 2011). Food stability among more disadvantaged rural communities can be reduced when climate and the commercial decisions of landowners interact. For example, if the frequency of droughts increases in a rural region of India and landowning farmers decide to switch to cotton or biofuels that require less water to grow, this can have significant impacts on the availability of the cheap staple foods on which impoverished local communities may depend.

'Access' includes access to adequate food for a nutritious diet. Several factors can increase nutritional inequalities by causing shortages of food. These shortages can be avoided by affluent families with the money and the means of transport to secure stocks of food, while disadvantaged communities have little flexibility. 'Utilization' refers to people having enough food but being unable to make use of it, such as if they are chronically ill. This can be further complicated in developing countries where out-of-pocket spending on medicines and health care can have devastating effects on already disadvantaged families, reducing their food budgets even further (Berman et al. 2010). Food insecurity is growing in many countries. Studies suggest that continuing population growth and increasing levels of consumption and demand will result in the world needing at least 50% more food by 2050 (Royal Society of London 2009; Godfray et al. 2010).

> Nevertheless, more than one in seven people today still do not have access to sufficient protein and energy from their diet, and even more suffer from some form of micronutrient malnourishment….the global population will continue to grow, yet it is likely to plateau at some nine billion people by roughly the middle of this century. A major correlate of this deceleration in population growth is increased wealth, and with higher purchasing power comes higher consumption and a greater demand for processed food, meat, dairy and fish, all of which add pressure to the food supply system. (Godfray et al. 2010)

1.07.5 Impacts on Agriculture

Agricultural productivity is not growing fast enough to meet the needs and demands of the world's populations for food, while the numbers of people without enough food are increasing in many countries. Food production will need to continually increase, and to do this more water will be required (Ludi 2009). The water resources of disadvantaged populations are already threatened in many developing countries, and increased droughts increase this threat. Food insecurity and its population health impacts are considered very likely to increase health inequalities between rich and poor nations and between population groups within countries. A global assessment of the potential impact of climate change on world food supply highlighted that any change in local and regional climatic conditions is likely to impose the greatest risk in terms of food security on the poorest countries with economies based heavily on agriculture (Rosenzweig and Parry 1994). In developing countries, farmers' adaptive efforts alone would do little to reduce the disparity between developed and developing countries.

Land suitability is also important. Currently, two-thirds of the world's land is constrained in its suitability for agriculture by being too cold, dry, steep, wet, or infertile. The proportion of land that is unsuitable in regions like southern Africa may also change in the future (Slater et al. 2007). Agriculture is a major part of the economies of many African countries and is often their biggest source of both gross domestic product (GDP) and foreign exchange, which again impact on their ability to feed their populations. Likewise in Mongolia, where livestock provide food and livelihood for very large numbers of people, large areas of land are also under threat of becoming unsuitable for pasture because of the threats of overgrazing and increasing aridity (UNDP 2011; Ministry of Nature & the Environment of Mongolia 2006).

Governments' attempts to protect the food security of their populations may be undermined to some extent by globalization and by the ability of other countries and large corporations to buy their land. Land suitable for agriculture in developing countries is sometimes taken over in large-scale purchases by transnational corporations and oil- or capital-rich but food-poor foreign governments. More than 50 Mha of land in Africa was acquired or negotiated for in this way in 2009 (Lambin and Meyfroid 2011). Food and biofuel grown on this land is usually destined for export, and the use of land in this way may conflict with the food and nutrition needs of some of Africa's more disadvantaged populations.

The impacts of climate on food security are complicated by a number of additional factors, not least the growth of some populations. Food prices are another factor – the World Bank estimated that in the 3 years from 2005, overall world food prices rose by 83% (World Bank 2011). In addition, globalization has resulted in significant interdependence of countries for access to food. The United Kingdom imports 90% of its fruit and about 60% of its vegetables and was therefore at risk of running short of fruit and vegetables in 2010 because of a ban on flights imposed by a volcanic ash cloud over Europe (Wray and Wearden 2010). The situation was illustrative of the potential impacts of extreme weather events on food availability in countries dependent on imported food, as well as on the economy of many developing countries where agriculture remains the largest employment sector and rural livelihoods depend on exporting food (WHO 2012).

Impacts on agriculture, food exports, and livelihoods may be made worse by background policy changes in one continent that can have large impacts in another. For example, an analysis by the World Bank in 2001 estimated that the implementation by the European Union of a new aflatoxin standard would reduce the health risk in Europe by 1.4 deaths per billion people, yet could decrease African exports by 64% (Otsuki et al. 2001). The importance of food safety standards to minimize risks to health is undeniable, but they need to be complemented by policies and actions that enable growers to attain these standards and safeguard their exports. The Overseas Development Institute proposes that unless mitigation policies designed in developed countries on issues such as biofuels and carbon markets consider their potential impacts on trade in developing countries and integrate them with global poverty reduction programs they risk exacerbating the existing restricted access of the poor to food resources (Prowse and Peskett 2008).

1.07.6 Water and Agriculture

Water is a key factor in agriculture, with the impact of climate change in increasing floods (McMichael et al. 2006) and drought being obvious examples (Bates et al. 2008). In Peru, for instance, a large proportion of the population is economically deprived, and the country was assessed as South America's most water stressed – in 2007, about 70% of Peru's population was living in the coastal desert, which held only 2% of the country's water (Rubio 2007). The region is losing large amounts of the glaciers that feed Peru's rivers thereby already facing significant droughts and their consequent impacts on agriculture. Water availability is also dependent on how it is conserved and utilized, on the amount allocated to agriculture by governments, and on how its utilization may be influenced by businesses.

1.07.7 Potential Risk of Temperature and Precipitation Changes on Agriculture: the Example of India

India's economy is highly dependent on agriculture, and a long-term rise in average temperature would affect many crops and hence people's livelihoods and the ability to feed their families. In one possible future scenario, the Indian Agricultural Research Institute projects that an increase in the atmospheric concentration of CO_2 may tend to increase yields of rice, wheat, legumes, and oilseeds. There may be improvements in yields of chickpeas, maize, sorghum, millets, and also (especially in the western parts of the coastal region) coconuts (Aggarwal 2011). However, increases in temperature may decrease yields of wheat, soybean, mustard, groundnut, and potato. Regional climatic changes have also been projected to lead to a possible 3% loss in potato production by 2020, and a possible 14% by 2050, so assuming an impact of 5% loss in production over 2010 figures by 2030 might be conservative. The quality of some crops may also be impacted. Aggarwal (2011) reported that temperatures above a mean of about 27 °C led to increasing decline in the quality of basmati rice (a highly valued rice with a notable fragrance and delicate flavor). This could potentially have an impact on farmers' and India's ability to compete in markets, with consequences for income and occupation and hence for health.

While rain is very important for the successful cultivation of rice and the amount of sunlight also influences rice yield in the last 35–45 days of its ripening period, temperature is the most crucial factor likely to impact on rice growing in India. Average annual temperatures have for decades had a positive influence on the yield of rice (which requires 20–40 °C to grow). Thirty degrees is the optimum in the daytime, and 20 °C at night. Bright sunshine within the lower temperature range during ripening helps the development of carbohydrate in the grain. Thus weather has a crucial role in both the growth and the availability of rice – a principal food crop in India.

Nights have been warmer in India over the past decade (an increase of 0.2 °C), and the FAO reported that during that period, India's rice yields leveled off. It has been established (Peng et al. 2004) that a 1 °C increase in night temperature leads to a 10% reduction in rice yield. When people in India become wealthier, they tend initially to eat more rice, but then as they become better off, their rice intake tends to decline as they eat other foods (Wassman and Dobermann 2007). Nighttime temperature increases have also been shown to decrease wheat yields – the duration of the period in which the grain fills begins to decline at night temperatures of $\geq$20 °C (Prasad et al. 2008). So reductions in rice (especially) and wheat availability, and a rise in the price, could have a large impact on poorer citizens in India, and widen the 'health gap' as their food intake may decline, unlike that of wealthier citizens. This could be a potential health disaster for many across the regions of India.

1.07.8 Inequalities in Food Security

A major public health study (Patz et al. 2005) concluded that the effect of climate change on food crop yield will probably exacerbate regional food supply inequalities. These effects are greatest in poorer populations at low latitudes, which face the most important climate-sensitive health outcomes (malnutrition, diarrhea, and malaria) and where vulnerability to climate effects is greatest (McMichael et al. 2004). Many analyses conclude that within those countries, the most deprived populations will be the hardest hit. One WHO study estimated that the DALY burdens per capita would be several hundred times greater in the poorer regions of Africa, parts of the Eastern Mediterranean region, and Southeast Asia than in Western Europe, North America, and the more developed regions of the Western Pacific (McMichael et al. 2004). The estimated mortality attributable to climate for the year 2000 was 0.15 deaths per million in WHO AMR-A Region (the most developed part of the Americas including Canada, Cuba, and the United States) but 65.79 in SEAR-D (eight countries in Southeast Asia including India, with high child and adult mortalities), 66.83 for AFR-D (a grouping of African countries with high child and high adult mortality), and 109.40 for AFR-E (African countries with high child and very high adult mortality).

1.07.9 Fish Stocks

Fish, crustaceans, and molluscs are very important food sources and are estimated to provide nearly three billion people with 15% or more of their animal protein intake. They can make up 50% of the animal protein supply of some small islands and West African states (Godfray et al. 2010). Seafood trade plays a major role for many deprived populations in developing countries by providing the incomes that enable them to buy enough food. Capture fishing provides just over half of the fish eaten by humans worldwide, while aquaculture contributes the rest (FAO 2010).

Climate-related factors have large impacts on fish stocks, affect the productivity of aquaculture systems, and increase the susceptibility of cultured fish to disease (Jaykus et al. 2008). The FAO's comprehensive analysis (Daw et al. 2009) of the impacts of climate variability show that very complex changes are expected in the world's fish stocks. Any significant increase in temperatures in different parts of the oceans could contribute to large changes in nutrient supply and fish stocks. While temperature is a very important factor, changes in ocean chemistry, including acidification from rising levels of CO_2, may have even more important impacts on animal and plant species (Harley et al. 2006).

Coral reefs play a key role in the aquaculture and fisheries of many islands. Crabbe (2009) stated that since reefs provide an environment in which one-third of marine fish are found and from which 6 million tons of fish were caught annually in 2008, increases in temperatures and continued changes in ocean chemistry may have large negative impacts on fish stocks during the twenty-first century by further damaging the world's coral reefs. Research suggests (Crabbe 2009) that increases in CO_2 levels in seawater may weaken the skeletons of some corals and reduce their ability to withstand erosion and compete for space. Corals bleach when exposed to prolonged above-normal temperatures, and this also can result in decrease in growth and recovery rates. While there is some evidence that corals can adapt, a possible future scenario is that the frequency of bleaching events could increase and become an annual process in most oceans. Agriculture and fisheries in the tropics are often associated with coral reef ecosystems in islands. Some of the poorer and less empowered countries closer to the equator may be more vulnerable, while also finding it harder to adapt. This is likely to be the case for countries depending on fisheries located in deltas or on coral atolls vulnerable to flooding, saline intrusion, or sea level rise. The FAO considered Sub-Saharan African coastal communities and small island states to be at high risk (FAO 2010). Asia was thought to be the continent most sensitive to the threat of changes in local and regional climatic conditions on aquaculture, while Africa and Latin America may have high growth potential for aquaculture, but to reduce risk would need the planning of adaptation and mitigation strategies (Cochrane et al. 2009). However, more than 90% of global animal aquaculture occurs in developing countries, many of them having the weakest institutional capacity to protect and improve ecosystem health (Smith et al. 2010).

Climate influences on fishing and aquaculture are compounded by economic factors impacting on the industries and affecting food security and inequalities. Rising demand among the European Union, Japan, and the United States, coupled with their ability to dominate pricing, may tend to decrease the amount of income and also the fish protein available to the smaller suppliers and the poorer populations in developing countries (FAO 2010). While the impact of price on different countries is complex, there is continuing strong pressure on developing countries to export seafood to wealthier countries, whose populations already tend to have better nutrition, thus increasing nutritional inequality. Developed countries and large private industries also wield a great deal of power over market access and regulation of food standards, and this may increase access and operational difficulties for smaller suppliers especially in poorer countries. There are also major pressures on current and future seafood stocks because of pollution of marine environments, especially in Southeast and East Asia (Nelleman et al. 2008). Around Pakistan's Karachi Coast, for example, marine disposal of untreated sewage and industrial effluent plus oil discharges from shipping have damaged mangrove forests and marine life and will have long-term impacts on fish (Government of Pakistan Environment Agency 2012). Abandoned, lost, and discarded fishing gear is an increasingly significant threat to fish stocks and their environments around the world, while over-harvesting and bottom trawling around the world are degrading fish habitats on a massive scale, with many species now being harvested close to capacity. At the same time,

> Illegal, unreported and unregulated fishing continues to threaten the long-term sustainable management of world fisheries. (FAO 2010)

There are also worldwide problems with fleets discarding unwanted fish on an enormous scale, including the killing and discarding of huge quantities of juveniles of economically valuable species, inevitably leading to species' decline. The pressures on species may be compounded by highly contagious aquatic animal diseases from poorly governed aquaculture, leading to serious losses and long-term damage (Nelleman et al. 2008).

These pressures vary widely between countries and in many developing countries can lead to fish populations being pushed beyond their limits. World Trade Organization rules may not differentiate between well- and poorly managed fisheries and aquaculture, and this can be compounded by poor governance in some developing countries. All these large impacts appear likely to complicate problems of food security for developing countries during a century in which sea warming is displacing fish stocks toward the poles and tending to reduce them in tropical waters (FAO 2010).

1.07.10 Livestock

Livestock productivity has been shown to be sensitive to temperature extremes (Nienaber and Hahn 2007), and farmers have to increase water and shade for their animals if mean temperatures increase. Animal reproduction may be adversely affected by increasing temperature and humidity (Epperson and Zalesky 1995). In Mongolia, where there is clear evidence of warming consistent with climate change (UNDP 2011), extreme weather events, drought, and associated land degradation, as well as overgrazing, have reduced forage yield, livestock production, and hence food availability. Its economy until recently had been almost entirely dependent on herding and agricultural production (M.A.D. Investment Solutions 2012), and severe drought and extreme cold have repeatedly exacted a heavy toll on the national economy. Drier conditions resulting from increased temperatures could increase the area of desert in Mongolia, a country where approximately 70% of the land is already classified as desertified, and reduce pasture by 10–30% (UNDP 2011). In 1999–2000 and 2000–01, the country was struck by two consecutive 'dzud' events, a Mongolia-specific winter disaster, which undermines the welfare and food security of the herding community through large-scale death and debilitation of livestock. Climate conditions in 1999–2000 led to 12 000 people losing all their herds, and in the following winter, 13% of Mongolia's livestock died, resulting in severe impacts on the economy and a GDP growth of 1.1% in 2000 and 1% in 2001 (M.A.D. Investment Solutions 2012). Declining herds are increasing starvation risk and extent among the population. When farmers have very low incomes, lower yields can have major impacts on the nutrition of their families.

1.07.11 International Policy Impacts

Increased global awareness of the entire spectrum of environmental risks is an essential precursor to the introduction of effective policy changes. However, some well-intentioned public responses to greater awareness of the human activities that generate greenhouse gases may have unforeseen negative consequences on other communities. One example is the concern regarding ’food miles,’ which measure how far a food has been transported to the dinner plate (Lang 2009). The concept originally developed to highlight to consumers the hidden environmental costs of food production, has more recently been shown to be misleading (McKie 2008). Food produced in a highly environmentally friendly manner in distant lands may account for less CO_2 emissions than locally produced food grown in an area of high use of fertilizers and mechanized farming. Changes in consumer behavior encouraged by concerns regarding food miles may also have other wider socioeconomic impacts. It has been estimated that stopping the import of fruit and vegetables from African countries would reduce the United Kingdom’s carbon emissions by less than 0.1%, while in 2008 it provided incomes for more than one million people living in rural Africa (Prowse and Peskett 2008) and thus could harm their livelihood if curtailed. Strategies should hence be developed that benefit the most disadvantaged people in developing countries while reducing environmental impacts. Similarly, increasing demand for biofuels as an alternative to petroleum products needs to be met in ways that do not increase food insecurity. If land is given over to biofuel crops on a large scale, they can displace important food crops. They can also drive up crop production costs such as rural labor and fertilizer. If this drives up the price of basic staple crops, the poorest people – often the urban poor – may be the first to suffer. Higher food prices have a direct impact on their ability to buy food (Godfray et al. 2010).

1.07.12 Food Safety

Climate impacts food safety, and long-term warming increases the risks (Jaykus et al. 2008). There are a number of causal pathways through which this occurs. Climate affects agricultural pests and diseases. Increasing ambient temperatures may be a contributing factor to the increased prevalence of insects, bacteria, viruses, and fungi, and hence this can impact on crop yields. Increased flooding can increase or cause chemical contamination of crops and hence foodstuffs (Jaykus et al. 2008). Any rise in average temperatures could also increase hygiene risks in food storage and distribution. Temperature and rainfall data have been used in Australia to predict numbers of cases of salmonellosis (Zhang et al. 2010). Climate affects disease transmission between vertebrate animals and humans by altering vector cycles and animal reservoirs and could conceivably result in new diseases. An increase in sea temperatures would provide more favorable environments for the growth of phytoplankton and for toxic algal blooms, which can accumulate in filter feeders, including the bivalve mollusks used by humans for food. Raised sea temperatures can also promote the uptake of mercury by fish and its accumulation via food chains. This may (Booth and Zeller 2005) lead to continuous increases in concentrations of methyl mercury in the tissues of people from communities with high intakes of fish, such as the Faroese. Raised sea temperatures are suspected of increasing the growth of *Vibrio* spp. (Paz et al. 2007), which are dangerous to humans and can be transmitted via infected fish or from immersion in contaminated water.

1.07.13 Vulnerability and Adaptation

Climate-related factors are likely to have major negative impacts on the ability of developing countries to gain food security for their most disadvantaged populations in the twenty-first century. There are many competing demands for land that could be used for agriculture, such as those from urbanization, and there are now no major new fishing grounds available (Godfray et al. 2010). While action on adaptation and mitigation within developing countries is needed, many countries that are vulnerable to the impact of climate on food security may not have the governance necessary to implement appropriate changes. Developing countries may also find their intentions constrained by the economic, legislative, and trade decisions of wealthier countries. Comprehensive strategies between countries combining agriculture, trade, aid, economic policy, earth sciences, public health, weather forecasting, and scientific advice to growers are needed. Action and strategy (such as those on ‘food miles’ (Lang 2009), for example) must be global, regional, and also local.

1.07.14 Regional Sensitivity

Studies highlight how strategies to address climate-induced impacts on food security must incorporate major factors such as trade, aid, and food prices and hence be modified at national and regional levels. However, they must also be sensitive and specific enough to be useful in mitigation and adaptation for specific geographical and population areas and would need to include demand modeling. In China, analyses suggest that agricultural water demand in the south and cropland soil-moisture deficit would decrease, while rain-fed crops in north and northeast China may face water-related challenges in the coming decades because of expected increased water demand and soil-moisture deficit and a projected decrease in precipitation (Tao et al. 2003). Similarly, there is a great difference in vulnerability to climate effects between individual regions in Peru (Rubio 2007). While the country has many harsh environments and an overall shortage of water, studies show that climate impacts in very different ways in different regions. In one region it resulted in droughts due to the disappearance of glacier melt water, while in another it led to the appearance of a new lake 150 km long in a desert, following El Nino-induced rainfall increases. Thus, to be effective, adaptation would require monitoring and action specific to localized areas with different crops and agriculture. While countries necessarily look to scientific innovation and highly technological agriculture for mitigation, Rubio (2007) points to the potential for a return to traditional locally developed agriculture such as raised fields, artificial swamps, and local crops that had long been adapted to high altitude environments but were displaced by more modern ones.

Mitigation needs to be not only informed by weather monitoring and prediction systems developed to meet farmers’ and growers’ needs but also supported by earth science ministries with intelligence about pests and about which food crops are suited to predicted weather conditions. This would, for example, help growers switch to alternative food crops rather than export crops like cotton, so as to help protect food security in their area.

A World Bank report highlighted that food needs may increase steeply by 2050, when the global population reaches nine billion against a background of reduced global average agricultural yields (World Bank 2012). Impact studies are pointing to severe difficulties particularly in Sub-Saharan Africa and South Asia where rural households are highly dependent on agriculture for their livelihoods and farming systems are highly sensitive to climate. It is recognized that agriculture is the sector most vulnerable to climate and at risk from changes in climatic conditions and is also itself a major cause of climate change, directly accounting for about 14% of greenhouse gas emissions (World Bank 2012) as well as altering the albedo, surface roughness, surface heat, and moisture fluxes due to large areas of land-use change (Marland et al. 2003; Pielke et al. 2011; Avila et al. 2012). Despite this, sustainable agricultural policies and practice can be a part of the solution, enabling people to feed themselves and adapt to changing climate while also contributing to its mitigation.

1.07.15 The Role of Farmers in Adaptation and Mitigation

The effects of climate variations are not new to farmers, but climate change has greatly increased their vulnerability. Farmers can nevertheless play a major role in adaptation and mitigation. ′Triple win′ interventions are possible that can generate higher yields, more carbon in the soil, and greater resilience to droughts and heat, resulting in poverty reduction and greater food security. However, achieving food security globally will require reengineering the complex food ′system′ through the active engagement of governments, science, business, the farming profession, and civil society at local, national, and international levels.

In November 2011, during the run up to the UN climate change talks held in South Africa, the independent ′Commission on Sustainable Agriculture and Climate Change′ (2011) made up of eminent scientists released a ′summary for policy makers,′ which highlighted the following action points:

1. Integrate food security and sustainable agriculture into global and national policies
2. Significantly raise the level of global investment in sustainable agriculture and food systems in the next decade
3. Sustainably intensify agricultural production while reducing greenhouse gas emissions and other negative environmental impacts of agriculture
4. Target populations and sectors that are most vulnerable to climate change and food insecurity
5. Reshape food access and consumption patterns to ensure basic nutritional needs are met and to foster healthy and sustainable eating habits worldwide
6. Reduce loss and waste in food systems, particularly from infrastructure, farming practices, processing, distribution, and household habits
7. Create comprehensive, shared, integrated information systems that encompass human and ecological dimensions

A collective effort to reshape food production access and consumption patterns worldwide is the only route to ensure a food secure planet in the future.

1.08.1 Introduction

Weather has been implicated as a causal factor in a wide range of diseases from early history. The first studies were observations of seasonal and geographical patterns in disease. When deaths became routinely reported, seasonal patterns were described in the earliest health statistics. More recently, sophisticated statistical techniques have been developed to quantify the acute effects of meteorological parameters to capture the day to day effects of weather (temperature) on human health. This chapter will describe the current state of knowledge regarding the effects of hot weather (environmental high temperature) on human health. The chapter focuses on impacts in high-income countries in temperate climate zones (Europe and North America).

We are now seeing a resurgence of interest in quantifying the effects of weather and climate on health because several major heat wave events have occurred, and there is increasing concern about anthropogenic climate change at the local, regional, and global levels. One of the impacts of climate change from greenhouse gas emissions is an increase in the future frequency and intensity of heat waves, as assessed by the Intergovernmental Panel on Climate Change (IPCC 2007, 2012).

1.08.1.1 Seasonality and Mortality

There has long been interest in the seasonal patterns of mortality (Alderson 1985). In the early nineteenth century, European countries exhibited peaks in mortality in the summer season. By the 1840s, England was showing winter peaks in mortality, with the exception of the years 1849, 1854, and 1866, when a large excess in summer deaths occurred because of major outbreaks of cholera (Farr 1852). Such changes in the seasonality of mortality in a population over time is also an illustration of the 'environmental risk transition' (Smith 1990). As countries develop economically, they undergo a change in risk patterns from those associated with traditional environmental hazards (lack of adequate water and sanitation and infectious and parasitic diseases) to modern risks (associated with an increase in chronic noncommunicable diseases) (Smith and Ezzati 2006).

A second seasonal mortality pattern has been observed in high-income populations, as modern risks then decline because of public health or other policy measures. Thus, a decline in excess winter mortality since the middle of the past century has been observed in many high-income countries. In the Netherlands, a 50% reduction in excess winter mortality between the 1950s and 1970 was reported (Kunst et al. 1991). Several authors have suggested that this is due to improvements in winter home heating (Sakamoto-Momiyama and Katayama 1971; Keatinge et al. 1989). This has lead to a progressive *deseasonalization* in mortality patterns as countries develop economically.

1.08.1.2 Temperature Regulation and Heat Injury

Healthy adult persons have efficient heat regulatory mechanisms that cope with increases in temperature up to a particular threshold. The body can increase radiant, convective, and evaporative heat loss by vasodilatation (enlargement of blood vessels in the skin) and perspiration. High temperatures cause some well-described clinical syndromes such as heat stroke, heat exhaustion, heat syncope, and heat cramps (Kilbourne 1997). Heat stroke occurs when the core body temperature reaches 40.6 °C and leads to multiple organ dysfunction and death. Heat stroke has a substantial case–mortality ratio, and progression to death can be very rapid (within hours). In survivors, there is an increased risk of long-term sequelae, including permanent damage to organs (Dixit et al. 1997), severe functional impairment (Dematte et al. 1998), and a risk of early mortality (Wallace et al. 2007).

Persons who are physically active in high temperatures are also at risk of heat illness (and exertional heat stroke). Occupational studies have also shown that at high ambient temperatures workers experience reduced cognitive ability and an increased risk of accidents and heat injury (see Occupational Health chapter, Kjellstrom et al., this volume).

When people sweat and do not drink sufficient water, they are at risk of dehydration and decreased urinary concentration. Low urine volume is a known risk factor for lithogenesis (formation of stones) and clinical renal colic (sudden severe pain associated with the passing of stones) (Boscolo-Berto et al. 2008). Although this is an acute effect of high environmental temperatures on health, it is rarely fatal and therefore not an important mechanism for heat-related mortality.

The majority of deaths that are 'attributed' to heat are not from heat stroke. Rather, they are defined retrospectively from the observed temperature–mortality relationship. Many causes of death are sensitive to heat effects. Studies of heat-related mortality in England and Wales (Gasparrini et al. 2012) and the United States (Anderson and Bell 2009) found that respiratory and cardiovascular causes were most sensitive, but nearly all major disease outcome groups show some sensitivity. Heat-attributable deaths are therefore defined statistically at the population level (using observed temperature–mortality functions or calculated as the number of deaths during a heat wave that are above a baseline/expected mortality level).

It is likely that there are several mechanisms by which a person may succumb during (or shortly after) a hot day, as the environmental temperatures places extra strain on a person whose health may already be compromised in some way. All other things being equal, any (chronic or acute) illness that compromises thermoregulation will increase the risk of heat-related death. If the exposure to heat is severe enough, even healthy people will succumb to heat stroke and death. Illnesses also compromise mobility, awareness, and behavior, and it has been shown that dementia and Parkinson's disease also increase the risk of heat-related mortality (Stafoggia et al. 2006). Overall, the epidemiological literature shows that the effect of temperature on mortality at the population level is different from that predicted by physiological processes in individuals. Therefore, epidemiological studies on cause-specific mortality can provide useful insights into the mechanisms by which daily temperature affects mortality.

Deaths certified as due to heat should be deaths from classical or exertional heat stroke, which may or may not be related to the weather (WHO 1977, 2007). Following the Chicago heat wave, attempts were made to improve the certification (reporting) of heat-related deaths (Shen et al. 1998). The US Centers for Disease Control and Prevention (CDC) regularly reports the incidence of heat mortality in United States (CDC 2006); 3442 deaths from exposure to extreme heat were reported during the 14-year period 1999–2003 (annual mean: 688 deaths). In two-thirds, the underlying cause of death was recorded as exposure to excessive heat; for the rest, hyperthermia was reported as a contributing factor. Deaths were higher in men than women in all age groups. The age distribution indicates that rates are highest in those older than 65 years and that deaths in children were relatively rare (228 deaths, 7% of total). The high mortality rate in adults (1810 deaths, 53% of total) probably indicates the importance of occupational exposures (see Occupational Health chapter). The states with the highest average annual hyperthermia-related death rates were Arizona (1.7 deaths per 100 000 population), Nevada (0.8), and Missouri (0.6) (CDC 2006).

1.08.2 Heat Waves and Their Impact on Health

The impact of hot weather becomes most apparent during extreme hot episodes (heat waves). In August 2003, an unprecedented heat wave affected most of central and western Europe. The overall estimate for excess mortality in August was just less than 45 000 deaths (Robine et al. 2008). The impact in France was considerable, with an estimated 15 000 excess mortality in a 20-day period (Hemon and Jougla 2003). A notable impact of the heat wave was the late detection of the mortality and morbidity impacts by the established public health surveillance system. Figure 1 illustrates the mortality peak (short-term increase in daily mortality) associated with the 2003 heat wave in London, United Kingdom. The excess mortality due to this event was estimated to be 616 in London and 2091 in England and Wales (Johnson et al. 2005).

In Europe, countries in southern Europe experience the highest temperatures and are also most sensitive to heat wave effects (Baccini et al. 2008). In Athens, in 1987, a 10-day heat wave resulted in 926 deaths that were classified as heat related. However, the excess mortality was estimated to be more than 2000 (Katsouyanni et al. 1988). In all urban areas in Greece except Athens, a 32.5% increase in mortality was observed in July 1987 compared to the average July mortality during 1981–86 (WHO 1977).

The midwestern region in the United States has also experienced several major heat wave events. The heat wave in Chicago in 1995 caused 514 heat-related deaths 12 per 100 000 population) and was associated with failures in the power and water supply systems as well as institutional failures in the heat wave response (Whitman et al. 1997). All heat wave deaths are considered to be preventable: the 1999 heat wave of similar magnitude caused 114 heat deaths in Chicago (Klinenberg 2002), indicating that 'adaptation' was relatively effective in reduing mortality, but not sufficient to prevent all the excess mortality. The highest sensitivity to heat-related mortality in United States is more in the northern cities.

1.08.3 Methods for Characterizing the Temperature–Health Relationship

Descriptions of seasonal patterns and individual events (episodes) only provide limited information on the causal processes of weather and climate effects on human health. Many nontemperature factors also vary on a seasonal basis. Heat waves are rare events and vary greatly in characteristics and additional

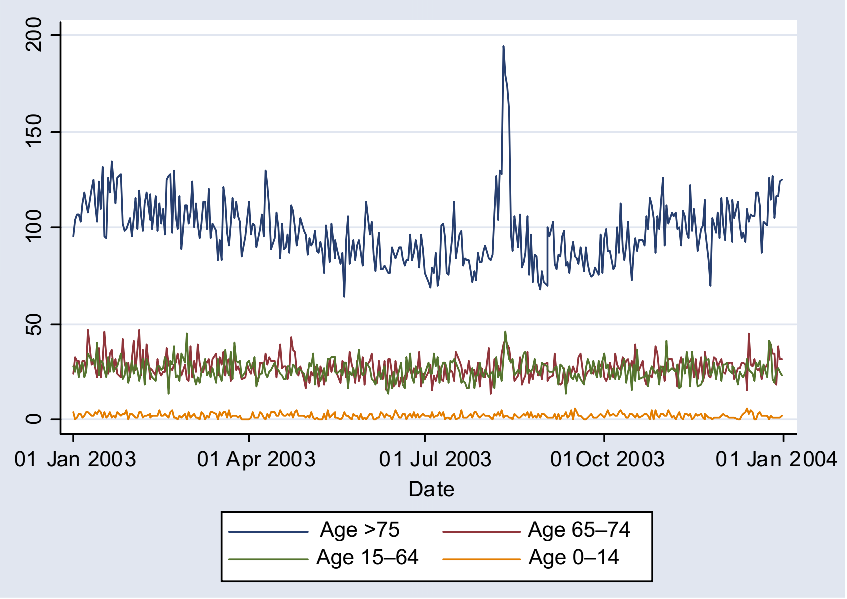

Figure 1 Daily mortality during the 2003 heat wave in London, UK. Source: Data from ONS.

exposures (e.g., air pollutants). A variety of methods have been developed to describe the effects of weather on humans. Early research in Europe focused on the classification of weather types that triggered particular symptoms. Recent developments have focused on quantitative models and increasing parameterization of the thermal environment. Epidemiological studies, however, which require long time series and population-level exposure indicators, have relied on daily data from weather stations that are routinely (but not always freely) available. Time series regression studies of acute effects are seen as the most robust approach to quantify the weather and health relationships (Basu 2009; Armstrong et al. 2011).

Populations in temperate climates show an increase in mortality risk above a population-specific threshold value. Figure 2 illustrates this relationship for London, United Kingdom. The key parameters in these studies are the heat 'threshold' value and the slope (or coefficient) of the change in mortality risk per unit change in meteorological parameter above the threshold value. There is generally less evidence for a threshold for cold effects (Analitis et al. 2008).

The whole population is assumed to be exposed to 'heat' and 'cold.' To date, population-based studies have used outdoor air temperature (or temperature-based indices), usually from a single weather station, as the exposure measures. Individual exposures to temperature are likely to relate more closely to indoor temperatures because people (at least in high-income countries) spend majority of their time indoors. However, this will depend on the population and climate. There are few studies that link indoor temperatures with health outcome risk, and these have mostly addressed cold exposures. Indoor temperatures are determined by housing characteristics and behavior as well as the outdoor temperatures. In addition, urban areas are often warmer than surrounding areas (i.e., have higher outdoor temperature) because of the urban heat island effect (see below).

Epidemiologists have generally preferred to use simple meteorological variables in their analyses, such as temperature, as the main exposure variable. Other meteorological variables can be included as confounders (humidity, barometric pressure, and wind speed). However, this is not straightforward because the meteorological variables are not independent. Therefore, some studies used indices that combine temperature with humidity, for example, apparent temperature (Steadman 1984).

The mortality attributable to a heat wave event is often estimated using episode analyses. That is, the attributable or 'excess' mortality can be estimated by subtracting the 'expected' mortality from the observed mortality. The expected mortality is calculated using a variety of measures, including moving averages and averages from similar time periods in previous years. Estimates are therefore sensitive to the method used to estimate the 'expected' mortality. Published studies have used different methods, and this makes comparison difficult.

A proportion of the 'acute' effect on mortality of heat waves may be due to the hastening of death in already ill persons by a few days or weeks. The mortality displacement effect can sometimes be seen in the lower-than-expected mortality immediately following a heat wave. The key question is, "What proportion of deaths was brought forward by more than a matter of days/weeks?" Several methods have been suggested for estimating the contribution of mortality displacement in daily time series models (Hajat et al. 2005). The extent of mortality displacement due to extreme temperatures has yet to be resolved.

1.08.4 Determinants of Vulnerability to Heat-Related Mortality

There are important differences in the temperature–mortality relationships between populations that cannot be explained by climate alone. The identification of these modifying factors is

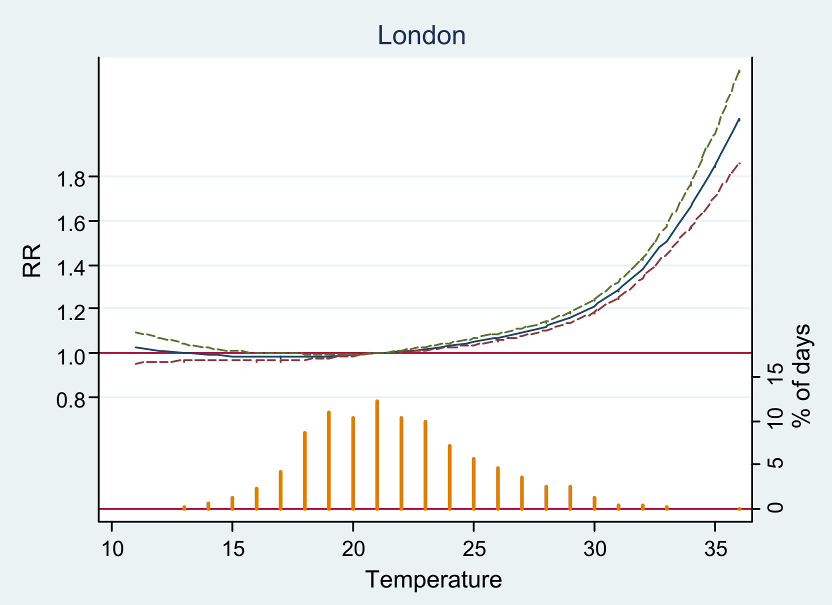

Figure 2 Temperature–mortality relationship in London. Source: Armstrong, LSHTM, Annu. Rev. Public Health 2008. 29: 9.1–9.15

an important research question, and it also enables 'heat wave' interventions to be targeted appropriately at high-risk groups (Figure 3). Most of the current information comes from time series studies and more recently, from case-crossover studies, which have been shown to provide comparable results (Basu et al. 2005).

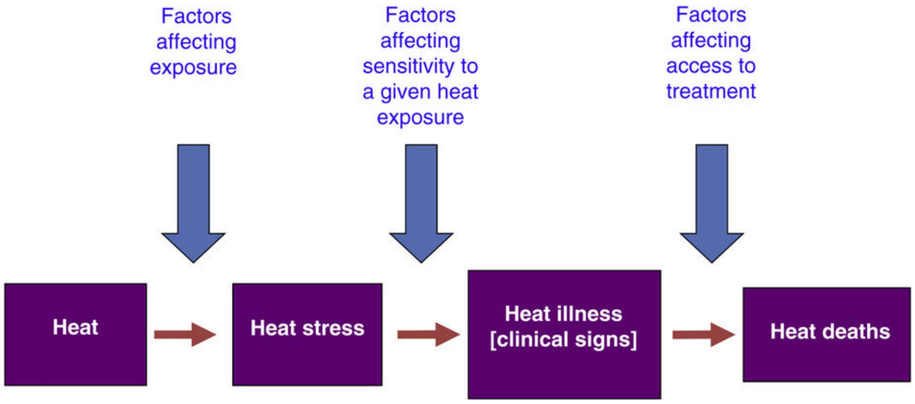
1.08.4.1 Age and Aging

The 'natural' patterns of aging (senescence) are associated with impairment of thermoregulation (Drinkwater and Horvath 1979) including reduced thermal perception (Collins et al. 1981). Some common medications are known to interfere with thermoregulation. At the population level, several studies provide strong evidence that age is a risk factor for heat- and cold-related mortality (Gasparrini et al. 2011; Hajat et al. 2007; Åström et al. 2011). Studies, however, vary at the age at which the vulnerability is shown to increase. Most population-based time series studies show an effect in adult age groups, but the effect is larger in those older than 75 years compared to other ages. Furthermore, it can be argued that chronological age is a poor indicator of risk, as it is really disability and cardiovascular fitness that are the main determinants of susceptibility to environmental heat.

Infants do not have well-developed thermoregulation and are sensitive to high temperatures. However, mortality due to heat in this age group is extremely low.

1.08.4.2 Gender

Overall, studies indicate that there is no difference in susceptibility to heat-related mortality between men and women (Alberdi et al. 1998). The evidence for heat-related mortality risk being greater in woman in high-income countries is



Factors affecting exposure
Factors affecting sensitivity to a given heat exposure
Factors affecting access to treatment
Heat
Heat stress
Heat illness [clinical signs]
Heat deaths

Figure 3 Factors determining the risk of heat-related mortality. Source: WHO 200x, Armstrong, B., and Coauthors, 2011: The association of mortality with high temperatures in a temperate climate: England and Wales. *J. Epidemiol. Commun. Health*, **65** (4), 340–345.

generally weak and inconsistent. However, because there are more women than men in the older age groups (because women live longer), the burden of heat-related mortality in women is greater than that in men. From a physiological point of view, women may be less heat tolerant than men, as they have, in general, higher core temperatures, skin temperature, heart rates, blood pressures, and set points for sweating than men (Havenith 1999). At the population level, such factors may not be important relative to age distributions, cardiovascular fitness, and other factors. It is possible that social and physiological factors are important in determining risk, and the social factors are likely to be very context specific. For example, in the 1995 heat wave in Chicago, men were at much greater risk of heat death than women (Whitman et al. 1997), and this was attributed to high rates of social isolation among men with low socioeconomic status (Klinenberg 2002).

1.08.4.3 Income and Deprivation

The results from studies in high-income countries in Europe have indicated that deprivation is not a major determinant of heat-related mortality (Stafoggia et al. 2006; Hajat et al. 2007; Kovats and Hajat 2008; Borrell et al. 2006; Ishigami et al. 2008). However, one study in Italy reported a higher risk in low-income groups (Michelozzi et al. 2005), but this study did not adjust for age or other confounders. Studies in the United States have been able to use a multicity dataset of daily mortality in order to get a more accurate description of individual-level determinants of heat risk. Mortality risks associated with extreme heat were greater in the black population, which is used a marker of socioeconomic status (Medina-Ramon et al. 2006). Individuals on low incomes are more likely to have a chronic disease or other medical risk factors, such as cardiovascular disease, and different types of housing, which will all modify the risk of heat-related mortality. It is therefore difficult to separate out the determinants of risk within this population, particularly where there is a lack of individual-level data on important risk determinants.

1.08.4.4 Housing Characteristics and Air-Conditioning

People spend a significant amount of time indoors, and so indoor temperatures are likely to play an important role in individual heat exposures, especially for the elderly and children. There is relatively little evidence for the types of housing (and thermal behavior) that increase vulnerability to heat-related mortality. Brick houses (with a high thermal mass), top floor apartments with no through ventilation, and closed windows have all been associated with an increased risk of mortality during a heat wave event (Mirchandani et al. 1996; Vandentorren et al. 2006). Informal housing is likely to be less thermally efficient.

Air-conditioning or comfort cooling has a direct role in reducing temperature exposures in individuals when they are in the cooled environment. There is good evidence that widespread use of air-conditioning in homes and care homes has reduced the mortality burden of heat waves in United States (Dixit et al. 1997; Marmor 1978; Kilbourne et al. 1982; Jones et al. 1982). The lack of air-conditioning may also be one of the reasons why there is more of an income gradient in heat-related mortality risk in United States than in Europe (O'Neill et al. 2005). A recent study found that the presence of air-conditioning reduced the risk of heat-related hospital admissions in California by up to 50% (Ostro et al. 2010).

The role of air-conditioning in reducing temperature-related mortality in populations outside United States remains unclear. It has also been suggested that widespread use of air-conditioning may reduce physiological acclimatization and therefore make people more susceptible to heat waves (O'Neill 2003). A high level of air-conditioning use also increases the risk of power failures during heat waves, which may exacerbate impacts on health.

Several studies in Europe have shown an increased risk in mortality for persons in residential care and nursing homes. The heat wave in 2003 caused a severe impact on elderly persons in hospital and residential homes in France. The mortality rate doubled in the those older than 75 years for persons living in *maison de'retrait* (Fouillet et al. 2006). In 2003, such institutions in France, Italy, and the United Kingdom were often without air-conditioning. A study in United Kingdom also found a much higher 'heat' risk in patients in nursing home and care home, with lowest risk in persons living at home (Hajat et al. 2007). The residents of institutions therefore represent an important high-risk group for heat wave interventions.

There is some evidence of the modification of risk by age group and by health status (frailty). In general, the risk of heat-related mortality increases with the level of disability, in the nursing home setting (Belmin et al. 2007). However, a study in France found the highest risk of heat-related mortality in the less frail patients. The authors suggested that medical care during the heat wave was directed toward 'the most vulnerable patients' and therefore, the risk was reduced in the most vulnerable group (Holstein et al. 2005).

1.08.4.5 Urban Factors

Studies from high-income countries indicate that urban populations are more sensitive than rural populations to heat-related mortality. This is assumed to be because urban populations experience higher outdoor temperatures caused by the urban heat island effect, but other factors relating to population susceptibility may also be important (Oke et al. 1997).

The relationship between cities and weather is complex. The urban heat island effect is caused by day time heat being retained by the fabric of the buildings and by a reduction in cooling vegetation. In temperate latitudes, this has the effect of raising night time temperatures by 1–5 °C (Oke 1995, 1973). Urban heat islands are measured as the difference in temperature between inside the city and the surrounding areas. The magnitude of the urban heat island is, in general, proportional to the size of the city. Urban heat islands are a factor in many cities but tend to be more severe in winter than in summer. Heat islands are dynamic in time and space and are therefore difficult to quantify either spatially or temporally for individual heat wave events. Although much is known about the factors of the built environment that increase temperatures, when estimating health effects within a city, confounding by housing type and socioeconomic factors becomes very important. Thus, few studies have demonstrated within-city effects of heat islands on heat-related mortality risk (Laaidi et al. 2012).

Future urbanization, including the increased use of air-conditioning, will increase the outdoor heat load in cities (Oke et al. 1997; Brazel et al. 2007). The relative impacts of these local, regional, and global anthropogenic changes, including warming from greenhouse gas and cooling from sulfates and other aerosols, are an emerging area of research (IPCC 2007; NRC 2005). One global model study estimated that warming due to urbanization and increased energy consumption was of comparable magnitude to the impact of doubled CO_2 in some regions (McCarthy et al. 2010).

1.08.4.6 Population-Specific Factors

There are now sufficient studies of heat-related mortality in separate locations in order to investigate the causes of the heterogeneity in observed heat effects between populations. There is good evidence that the heat threshold is related to the local climate, and this reflects the acclimatization of the population. A study of 11 cities in United States found that level of air-conditioning was inversely related to the heat slopes (Curriero et al. 2002). An analysis of the heat slopes in the Isotherm study found no significant association with a range of variables, including latitude, gross national product, mean annual temperature, or proportion of elderly (McMichael et al. 2008). A meta-regression analysis of heat slopes in 64 locations, adjusted for the heat threshold, found that increasing population density, decreasing total GDP of city, and increasing the percentage of people aged 65 years or more were all independently associated with an increase in the heat slope (Hajat and Kosatsky 2009). Thus, population characteristics (such as age profile and income) are likely to be important determinants of heat-related mortality.

1.08.4.7 Heat, Violence, Suicide, and Accidents

There are very few daily time series studies of the association between ambient temperature and mortality/morbidity from injuries (intentional or unintentional). In United Kingdom, injuries (e.g., falls) increase in cold and icy weather in the elderly (Levy and et al. 1998). A study of temperature-related mortality in England and Wales found that high temperatures increased the risk of mortality from injuries in adults and the elderly (Hajat et al. 2007). Injuries in children increase in the summer, as they are more likely to be playing outside (Christoffel 1985; Masterson et al. 1993).

Regarding intentional injuries, there is less robust evidence for temperature effects. One time series study found an effect of high temperatures on suicide mortality (particularly by violent methods) in England and Wales (Page et al. 2007). A study in Taiwan also found an effect of high temperatures on violent suicide (but no effect on nonviolent suicides) (Lin et al. 2008). However, the mechanisms were not really clear and countries often have different seasonal patterns in suicide mortality. Evidence for high temperature effects on violence is disputed by psychologists (Rotton and Cohn 2000). Epidemiological studies show inconsistent results, and overall, the evidence is not convincing. A study in Adelaide, Australia, found an increase in ambulance callouts for assault in adults on heat wave days compared to nonheat wave days (Nitschke et al. 2008). However, a study of accident and emergency visits for assault in Cardiff, UK, found no significant correlation with weather factors (temperature, rainfall, and sunlight hours) (Sivarajasingam et al. 2004).

1.08.4.8 Air Pollution and Heat Effects

Simultaneous exposure to air pollutants and both high and low temperatures occur when atmospheric processes that occur in the lower atmosphere are unable to disperse rapidly enough the air pollutants that enter the air space above an urban area. High pollutant concentrations are associated with stable atmospheric conditions in both winter and summer (slow moving or static high pressure areas – anticyclonic conditions). Higher summer temperatures (and ultraviolet radiation) accelerate the formation (and destruction) of the photochemical air pollutants, such as ozone and nitrogen oxide. Thus, ground-level concentrations of ozone are determined by complex atmospheric chemistry driven by ultraviolet light, temperature, and the presence of other pollutants.

Few studies have successfully differentiated weather-induced and pollution-induced daily mortality. In studies of heat-related mortality, air pollutant exposure is a *confounder* because it is associated with both daily variations in temperature (exposure) and daily variations in mortality (outcome). However, air pollutant exposure is also a probable *interactor*. There is only limited evidence of a physiological synergistic effect between temperature and pollutants (Katsouyanni et al. 1993). A recent review found that of the 12 US studies that studied the role of pollutants in temperature–mortality associations there was little evidence of pollution acting as a confounder or effect modifier (Basu 2009). Some studies have found evidence for confounding and interaction between temperature and ozone effects in United States (Ren et al. 2008) and in France during the 2003 heat wave (Filleul et al. 2006).

1.08.5 Risk Assessment for Current and Future Burdens of Heat-Related Mortality

Future populations are likely to be exposed to increasing outdoor temperatures. The implications to human health from such changes have been evaluated primarily in the context of climate scenarios from greenhouse gas forcings (IPCC 2012). Other aspects of climate change (e.g., heat islands) are less well studied. Many factors have a substantial influence on the burden of mortality and morbidity attributable to the 'direct' effects of temperature, which can be considered determinants of population vulnerability and adaptive processes. In epidemiological terms, such factors are effect modifiers of the temperature–mortality relationship.

Health impact assessments of climate change (due to greenhouse gas emissions) have been undertaken at city, national, regional, and global levels. Most future climate impacts assessments use a scenario-driven approach to take into account the uncertainty about future climate and the future world in which those climates will be experienced. Scenarios are plausible and often simplified description of how the future may develop, based on a coherent and internally consistent set of assumptions about driving forces and key relationships. Climate scenarios are generally derived from the output of global or regional climate models. Sometimes the model output is downscaled to local areas (such as cities), but it is not clear if this reduces the uncertainty in the future projection.

As nearly all aspects of our natural, physical, and social environment will change in the future, it is important that these changes are reflected in the scenarios used in climate impacts studies. In practice, however, only population growth and economic growth (in GDP per capita) have been quantified and routinely included in climate impact studies. Several studies have now been published that estimate future heat-related mortality under a range of climate scenarios (to estimate a set of plausible future changes in local temperature exposures) (Huang et al. 2011). Some (but not all) use population scenarios to estimate the future total population and/or the proportion of people belonging to older age groups, who are much more susceptible to heat-related mortality. A common limitation of these studies is that they must make assumptions about how future populations will respond to exposure to high temperatures, including the rate of acclimatization. The studies so far have focused on cities in high income populations and show that heat-related mortality is likely to increase, even when some acclimatization is assumed (Huang et al. 2011; Kinney et al. 2008).

Populations in Europe and North America are aging. In addition, the number of persons with chronic diseases is anticipated to increase. High-income populations are expected to experience a high burden of disease from both cardiovascular and other chronic diseases such as diabetes in the next few decades. These trends are likely to increase the susceptibility to heat (Table 1) (O'Neill and Ebi 2009). In contrast, populations may become less sensitive to temperature extremes due to improvements in the underlying health of the population and improvements in the infrastructure, particularly the uptake of air-conditioning or passive cooling systems to reduce indoor temperatures.

Table 1 Risk of heat-related mortality associated with chronic disease category

Chronic disease category	*Risk of heat-related death*
All respiratory	?
COPD	+
Asthma	+
Neurological damage, Parkinson's disease, etc.	+++
Schizophrenia, psychotic illnesses	++
Dementia, Alzheimer's disease	+++
Diabetes, renal disease	+++
Previous stroke	++
Obesity	+ (elderly) ++ (adults)
Ischemic heart disease	++

+, small risk
++, moderate risk
+++, high risk

1.08.6 Implications for Public Health and Environmental Policy

The impacts on policy and the implementation of specific heat wave public health measures have undergone significant changes in the past decade. Since the 2003 event, most countries in western Europe have implemented some specific public health measures for heat waves, mostly in the form of a heat health warning system. Lessons learned following the event included the lack of an intervention plan for heat waves and the lack of coordination between the social services and health agencies. In addition, very few care homes (*maison de'retrait*) had air-conditioning or other space cooling, and these buildings simply became too hot. The relatively rapid development of these systems can be seen as the success of public health. However, there is still very limited evidence on the most effective ways to prevent heat-related mortality, particularly in community settings (Hajat et al. 2010).

Heat health warning systems use meteorological forecasts to reduce the impact of heat waves on human health and have developed a range of indices to trigger warnings and other actions (Hajat et al. 2009). Epidemiological analyses are required to identify the temperatures at which weather conditions become sufficiently hazardous to human health in a given population to warrant intervention. In practice, this threshold should relate to both the population sensitivity and to operational factors (e.g., is the system designed to protect against only extreme heat events or can it be triggered each year?). Warnings issued to the general public during heat waves reinforce the health messages about heat avoidance behavior. A review of heat health protection messages found that these messages vary between systems (Hajat et al. 2010). Furthermore, the evidence base from some advice is not very clear, such as advice about the use of fans and intake of fluids or salt.

Some cities (e.g., Rome) have an active component of the heat warning systems that include health professionals identifying and contacting high-risk individuals. Heat effects are quite broadly distributed in the population and identifying such individuals is very difficult. Potentially, a very large numbers of individuals need to be contacted. A recent review of current heat avoidance interventions confirmed the importance of valid information on individual risk factors (Hajat et al. 2009). Another limitation of heat warning systems is the recognition that heat-related mortality is not confined to recognized 'heat wave' days (Hajat et al. 2006).

Populations would benefit from heat-related public health actions, which would also need to be targeted at protecting children. However, it is not clear what the best methods for intervention might be. It may be that long-term interventions targeted at improving living conditions would be the most beneficial and cost-effective measures. Without more specific information on the population subgroups most vulnerable to heat-related mortality, it is difficult to make specific recommendations for public health interventions. It is clear that heat intervention plans should be best suited for local needs, through coordination between the local public health agencies, social services, voluntary agencies, and the national weather service.

Another approach to reducing heat-related mortality has focused on the built environment and mitigating the urban heat island effect. Within a given city, the hottest areas are those with the tallest buildings, with the greatest density of buildings, and without green spaces. Therefore, measures to reduce the urban heat islands have focused on the following measures:

- Increasing green spaces and planting trees in streets (trees not only provide shade but also improve air quality)
- Increasing ventilation and air flow (which also improves air quality)
- Increasing the albedo of a city (e.g., painting roofs white)
- Decreasing anthropogenic heat production (e.g., reducing energy-intensive air-conditioning and enhancing natural space cooling of buildings).

The urban heat island is an inevitable consequence of urban development and is an issue for rapidly expanding cities in low- and middle-income countries (Rydin et al. 2012). Appropriate and climate-friendly urban planning, however, may help reduce the magnitude of the urban heat island, but urban planning is often weak in this context. Overall, the benefits of some interventions (e.g., tree planting and increasing albedo) in reducing outdoor temperatures have been shown in some settings. Other benefits (in terms of economic benefits, amenity value, and welfare) of these measures are also apparent. For example, the benefits of tree planting projects include shading, cooling due to evapotranspiration, dust control, runoff control, consumption of carbon dioxide, and water conservation.

1.08.7 Conclusions

The ability to live in different climates around the world is seen as a triumph of human ingenuity and adaptability. Changes in housing, clothing, and behavior allow humans to adapt to climates ranging from the tropics to polar regions; however, even with adaptation, there is a current burden from high-temperature events in terms of premature death, heat injuries, and other health effects. More research is needed to describe the determinants of vulnerability to heat-related mortality and to design interventions that will reduce current and future impacts on health. Such interventions should be cost effective and have environmental benefits, particularly with respect to energy efficiency (Wilkinson et al. 2007). The challenge is to create and maintain healthy cities and healthy houses that protect against both heat and cold and other environmental hazards (Rydin et al. 2012).

1.09.1 Introduction

Overall, up to 40% of the general population has been reported to suffer from hay fever (Bousquet et al. 2008) with 23–30% of the population being affected in Europe (Bauchau and Durham 2004). Moreover, the prevalence of allergic rhinitis has increased markedly over the past decade worldwide (Katelaris et al. 2011). Up to 37% of teenagers are affected by asthma symptoms, making it the most common chronic diseases in childhood (ISAAC 1998). Absence from school and limitations in activities are some of the common consequences of asthma. In 2004, the estimated cost of asthma symptoms among children in the European Union was €3000 million, indicating that asthma in children is a substantial disease burden for society (van den Akker-van Marle et al. 2005). Adult asthma is also very frequent, with 15% of adults suffering from this condition. Asthma prevalence varies worldwide (Asher et al. 2006).

For the past 40 years, the prevalence of asthma has in general increased and is still increasing worldwide in parallel with other indices of allergy (Law et al. 2005). However, the falls in some indices of asthma in children in some Western countries with the prevalence of the disease was high, suggesting that the increase may be coming to an end. The leveling-off could be explained by the fact that in such countries all susceptible individuals have become allergic (von Hertzen and Morais-Almeida 2005). In addition, effective asthma therapy has decreased asthma consultation rates and thus the prevalence rates. Asthma is still increasing in developing countries (Asher et al. 2006).

1.09.2 Pollen and Allergic Respiratory Diseases

Pollen grains, which are a causative agent of allergic respiratory responses in patients with pollen allergy, are amongst the commonest allergens, and pollen allergy, because of its elevated prevalence and associated costs, is now a public health problem (D'Amato et al. 2007). In the European Community countries, between 8 and 35% of young adults show IgE serum antibodies to grass pollen allergens, which are the most commonly encountered (Burney et al. 1997) and the cost of pollen allergy in terms of impaired work fitness, sick leave, consulting physicians and drugs, is very high (Pawankar et al.).

Both grass and birch pollen are among main causes of exacerbation and development of rhinitis. Grass pollen counts aggravate seasonal allergic rhinitis in terms of symptoms in a French nationwide sample (a rise of 60 grass pollen grains per cubic meter increased the risk of suffering from a severe seasonal allergic rhinitis by 8% after adjusting for potential confounders and air pollution levels (Annesi-Maesano et al. in press)). Results were also confirmed in the subsample of individuals with documented sensitization to grass pollen. In addition, exposure of the mother during pregnancy to high levels of birch pollen resulted in a tendency toward increased risk of sensitization to the same allergen and symptoms of atopic disease in children with atopic heredity (Kihlström et al. 2003).

So far, the risk of pollen has been scarcely quantified at the population level in the case of asthma. We observed a significant short-term, i.e., within a week, association between grass (Poaceae) pollen counts and consultations for asthma attacks as seen by general practitioners. Adjusted relative risk for Poaceae was 1.54 (95% CI: 1.33–1.79) with an inter-quartile range increase of 17.6 grains/m^3 during the pollen season (Huynh et al. 2010).

The genus *Ambrosia*, which includes both *Ambrosia artemisiifolia* (short or common ragweed) and *Ambrosia trifida* (giant ragweed), has long been recognized as a significant cause of allergic rhinitis. A large random skin test survey demonstrated that 10% of the US population was ragweed sensitive (Gergen et al. 1987). Moreover, Ambrosia pollen levels were significantly related to asthma and rhinitis in a study based on a symptoms diary and peak expiratory flow rates (Newhouse and Levetin 2004). In Europe, ragweed sensitization is increasing, together with the invasion of this weed, especially in central and eastern areas, where it is now presenting a public health issue (Tosi et al. 2011).

1.09.3 Air Pollution and Allergic Respiratory Diseases

Despite some differences in the air pollution profile and decreasing trends of some key air pollutants, namely, industrial toxicants, air quality is an important concern for public health in cities throughout the world.

The most abundant components of air pollution in urban areas are nitrogen dioxide, ozone, and particulate matter (PM). Sulfur dioxide is particularly abundant in industrial areas. It is estimated that more than 50% of the population of the United States lives in areas where levels of ozone, nitrogen dioxide, sulfur dioxide, and particulates exceed current National Ambient Quality Standards, as monitored by the US Environmental Protection Agency (Dockery et al. 1993; Dockery and Stone 2007) With its particulate and gaseous emissions, road traffic is the main contributor to air pollution in most urban areas (Laumbach and Kipen 2012). Although associations between air pollution and respiratory diseases are complex, recent epidemiological studies have led to an increased recognition of the emerging importance of traffic-related air pollution in both developed and less-developed countries (Laumbach and Kipen 2012). A number of experimental and epidemiological studies confirmed the negative effect of urban air pollution on human health and on allergic respiratory diseases (D'Amato et al. 2010), and climate may impact these effects (D'Amato and Cecchi 2008).

1.09.3.1 Nitrogen Dioxide (NO_2)

Car and truck exhausts, together with power plants, are the most significant sources of outdoor NO_2 (EPA), which is a precursor of photochemical smog found in outdoor air in urban and industrial regions and, in conjunction with sunlight and hydrocarbons, results in the production of ozone. Like ozone, NO_2 is an oxidant pollutant, although it is less chemically reactive. NO_2 exposure is associated with increased emergency room visits, wheezing, and medication use among children with asthma (Lipsett et al. 1997; Gauderman et al. 2005). Controlled exposure studies of asthmatics have found that NO_2 can enhance the allergic response to inhaled allergens. NO_2 concentrations in ambient air are also reportedly associated with cough, wheezing, and shortness of breath in children (Rosenlund et al. 2009). In the Swiss SAPALDIA study, long-term exposure to outdoor residential NO_2 was associated with a decrease in lung function and a lifetime history of doctor-diagnosed asthma in adults (Ackermann-Liebrich et al. 1997). A Japanese cohort study also reported an association between NO_2 levels and asthma incidence (Shima et al. 2002). In contrast, a Norwegian study found no association between-modeled NO_2 exposure at the birth address and doctor-diagnosed asthma in a large cohort of children (Oftedal et al. 2009).

A large epidemiological study on more than 18 000 young adults suggests that exposure to high temperature and outdoor NO_2 increases the risk for allergic rhinitis (de Marco et al. 2002).

1.09.3.2 Ozone (O_3)

Ozone is generated at ground level by photochemical reactions involving nitrogen dioxide, hydrocarbons, and ultraviolet (UV) radiation. Ozone inhalation induces epithelial damage and consequent inflammatory responses in the upper and lower airways, as shown by an increase in the levels of inflammatory cells and mediators in nasal and bronchoalveolar lavage (Peden et al. 1995; Lin et al. 2008).

The acute health effects of exposure to ambient ozone have been examined in many geographical regions (Ebi et al. 2008). Potential adverse effects include decrease in lung function, airway inflammation, symptoms of asthma, increases in hospitalization due to respiratory diseases, and excess mortality (Bernstein et al. 2004). Ozone exposure has both a priming effect on allergen-induced responses and an intrinsic inflammatory action in the airways of allergic asthmatics (de Marco et al. 2002; Peden et al. 1995; Lin et al. 2008; McConnell et al. 2002).

In the long term, continuous exposure to high ozone levels impairs respiratory function (Mudway and Kelly 2000) and causes or exacerbates airway inflammation in healthy subjects (Schelegle et al. 2009) or atopic asthmatics, respectively. At the population level, long-term exposure to ozone may reduce lung function in school children and adults and increase the prevalence of asthma and asthmatic symptoms (Peden et al. 1995; Lin et al. 2008; Jorres et al. 1996). In addition, studies have long shown that asthma can be exacerbated by ozone, as measured by increased visits to emergency departments on days with higher levels of ozone and other pollutants (D'Amato et al. 2005; McCreanor et al. 2007). Moreover, an increased asthma prevalence has been observed in milder climatic areas, possibly due to the positive effect of air temperature on ozone synthesis (D'Amato and Cecchi, 2008; Shea et al. 2008).

1.09.3.3 Traffic-Related Air Pollution, Particulate Matter, and Diesel Exhaust Particles

There is evidence that living near high-traffic roads is associated with impaired respiratory health including asthma (Gauderman et al. 2005; Horak et al. 2002; Gauderman et al. 2007). First, McConnell et al. (2002) observed that the incidence of new diagnoses of asthma in children is associated with physical exercise in areas with high concentrations of ozone and PM. Since then, other prospective cohort studies have indicated that long-term exposure to traffic pollution could contribute to the development of asthma-like symptoms and allergic sensitization in children (Laumbach and Kipen 2012). All surveys reported associations with at least some of the studied respiratory symptoms including asthma. Potential long-term effects of traffic exhaust on the development of allergies sensitization were only assessed in the four European birth cohorts (Bråbäck and Forsberg 2009). Long-term exposure to outdoor air pollutants had no association with sensitization in 10-year-old school children in Norway (Oftedal et al. 2007). In contrast, German, Dutch, and Swedish preschool children had an increased risk of sensitization related to traffic exhaust despite fairly similar levels of outdoor air pollution as in Norway (Morgenstern et al. 2007; Brauer et al. 2007). Traffic-related effects on sensitization could be restricted to individuals with a specific genetic polymorphism. Assessment of gene–environment interactions on sensitization has so far only been carried out in a subgroup of the Swedish birth cohort (Melén et al. 2008). These studies, however, are flawed by the fact that no objective assessment of air pollution concentration was available. Individual exposure was estimated by the distance from the highways.

PM is a mixture of organic and inorganic solid and liquid particles of different origins, size, and composition (Ristovski et al. 2012). It is a major component of urban air pollution and has the greatest effect on health. Penetration of the tracheobronchial area is related to particle size and the efficiency of airway defense mechanisms. Ultrafine particulate matter (UFP), with diameters of 0.1 μm or less, is a major component of emissions from vehicles. These particles accumulate into larger fine PM with a diameter $\leq$2.5 mm ($PM_{2.5}$) within short distances from the point of release (Laumbach and Kipen 2012). PM_{10} (particulate matter with a diameter $\leq$10 mm) consists of $PM_{2.5}$ and larger particles of mainly crustal or biological origin, including many aeroallergens. On the basis of epidemiological and laboratory studies, $PM_{2.5}$ appears to be more potent toward respiratory and cardiovascular diseases compared with PM_{10} (Gauderman et al. 2007). PM_{10} can penetrate the lower airways, and $PM_{2.5}$ is thought to constitute a notable health risk since it can be inhaled more deeply into the lungs at the alveolar level (Oberdörster et al. 2005). Human lung parenchyma retains $PM_{2.5}$, whereas particles larger than 5 μm and smaller than 10 μm only reach the proximal airways, where they are eliminated by mucociliary clearance if the airway mucosa is intact (Peden 2008).

A large portion of urban PM originates from diesel engines, the source of diesel exhaust particles (DEPs), which includes other components such as polycyclic aromatic hydrocarbons (PAH). DEPs account for up to 90% of airborne PM in the world's largest cities (Shah et al. 2004; Rield and Diaz-Sanchez 2005) and are composed of fine (2.5–0.1 μm) and ultrafine (0.1 μm) particles, which can also coalesce to form aggregates of varying sizes. Although there were slight reductions in PM_{10} concentrations in Europe in the period 1999–2009, 20% of the urban population still lived in areas where the EU air quality 24-h limit value for PM (PM_{10}) exceeded that in 2009 (EEA 2011).

PM_{10} levels have been associated with early asthma exacerbations in children with persistent disease and with higher prevalence rates even after having considered the dispersion of the particles (Pénard-Morand et al. 2010). Although there is extensive evidence that ambient air pollution exacerbates existing asthma, the link with the development of asthma is less well established, as few studies provide extensive exposure data. In the past few years, birth cohort studies from Germany, Holland, and Sweden, which followed children during childhood, have suggested a positive relationship between PM and physician-diagnosed asthma (Brauer et al. 2007; Gilmour et al. 2006; Morgenstern et al. 2008; Nordling et al. 2008). Researches have elucidated the mechanisms whereby fine particles induce adverse effects; they appear to affect the balance between antioxidant pathways and airway inflammation. Gene polymorphisms involved in antioxidant pathways can modify responses to air pollution exposure (Sacks et al. 2011). Acute exposure to diesel exhaust causes specific effects, such as irritation of nose and eyes, headache, lung function abnormalities, fatigue, and nausea in acute exposure, whereas chronic exposure is associated with cough, sputum production, and diminished lung function (Rield and Diaz-Sanchez 2005).

Studies have demonstrated inflammation in the airways of healthy individuals after exposure to diesel exhaust and DEPs, and elevated expression and concentrations of inflammatory mediators have similarly been observed in the respiratory tract after diesel exhaust and DEP exposure (Ghio et al. 2012) Earlier studies showed that DEPs also cause respiratory symptoms and modify the immune response in subjects with atopic disease and can interact with aeroallergens to enhance antigen-induced responses (Diaz Sanchez et al. 1997). Even though an increased sensitivity of asthmatic individuals to the proinflammatory effects of DEPs has not been confirmed, some studies have shown a bigger effect of exposure to high-traffic roads in asthmatics compared to nonasthmatic subjects, also accompanied by increases in levels of biomarkers of neutrophilic inflammation (McCreanor et al. 2007).

1.09.4 Possible Effects of Climate on Respiratory Allergy

The effects of climate on allergic diseases in general (Shea et al. 2008), especially respiratory allergic diseases (D'Amato and Cecchi 2008; Ayres et al. 2009; US EPA 2008), have recently been reviewed. Taking into account the main environmental factors affecting respiratory diseases and their plausible changes under a subset of different possible future regional and local climate conditions, some negative effects are possible. The impact of pollen, spores, and pollutants might be greater, with children possibly being the more exposed and susceptible population (Schmier and Ebi 2009).

Climate might affect the prevalence of respiratory allergic diseases through an effect on important environmental factors for these diseases, such as aeroallergens and pollutants. Climate variability and any longer term change affect pollen and spore production by plants and fungi as well as different phenological events and, at the same time, the different aerobiological processes (emission, dispersion and/or transport, and deposition) of aeroallergens.

Plant biology is directly affected by rising carbon dioxide (CO_2), (CO_2 being the sole supplier of carbon for photosynthesis) and by temperature and water availability, among the most relevant environmental factors affecting phenology. Since the concentration of atmospheric CO_2 is projected to increase in the next decades, a number of effects on plants involved in human health can be anticipated in the future (Ziska et al. 2009).

Climate, including possible changes in regional and local climate statistics as well as the increase in the atmospheric concentration of CO_2, could affect the allergic population

Table 1 Examples of climate phenomenon related to air pollution and allergens and possible health impact

Examples of climate phenomenon	*Possible effects on air pollutants and allergens*	*Allergic effects*
Fewer cold days and nights over most land areas	None	Possible impact on asthma through reduction of airways infections
Warmer and more frequent hot days and nights over most land areas	● Earlier pollen season onset ● Increased pollen season duration ● Increased pollen production ● Altered plant and pollen distribution (invasion of plants)	Increased asthma and rhinitis symptoms
Warm spell and heat waves	Air pollution ● Increased levels of particulate matter and O_3	Increased risk of development and exacerbations of allergies
	Pollen ● Earlier pollen season onset ● Altered plant distribution (invasion of plants and neophytes) ● Increased pollen production/content/allergenicity ● Increased pollen season duration	Increased risk of development and exacerbations of pollen allergies
Heavy precipitations	Increase in dampness and molds	Increased risk of development and exacerbations of allergies
Drought increases	Altered plant distribution (invasion of plants)	Increased risk of development and exacerbations of pollen allergies
Extreme weather events (wind)	Long-distance transport of pollens	Increased risk of development and exacerbations of pollen allergies

through (1) increased levels of air pollutants and (2) altered spatial and temporal distribution of allergens (Table 1). In this chapter, we summarize and discuss evidences on the interactions among climate, air pollution, airborne allergens, and respiratory allergy.

1.09.4.1 Possible Effects on Pollutant Levels

Climate factors influence regional weather regimes (wind patterns, and amount and intensity of precipitation, and air temperature) and, as a consequence, severity and frequency of air pollution episodes (Ayres et al. 2009). Moreover, it can affect anthropogenic emissions (e.g., increase in energy demand for space cooling) and enhance urban heat island effect, inducing an increase in some secondary pollutants (i.e., ozone). Finally, there can be an indirect effect on natural sources of air pollutant (e.g., decomposition of vegetation, soil erosion, and wildfires) (Confalonieri et al. 2007).

As tropospheric ozone is formed in the presence of UV and high temperatures, its concentrations increase with the increase of air temperature. In fact, tropospheric ozone concentrations are increasing in most regions (Chen et al. 2004), and this trend is expected to continue over the next 50 years (Prather et al. 2003).

Heterogeneous composition of PM, however, makes a projection of the effects of climate on its concentration very difficult. The crucial importance of local climatic conditions makes the projections even more troublesome and challenging. Other sources of PM can be affected by changes in temperature and precipitation, such as forest fires (Moore et al. 2006).

SO_2 and NO_x oxidize in the atmosphere in reaction with water vapor in air to form sulfuric acid and nitric acid, respectively, and the oxidation rate is accelerated by higher temperature. An overall warming climate might induce an increasing potential of acid deposition (e.g., acid rain) (Bernard et al. 2001) that might be counterbalanced by a decrease of SO_2 emissions, for example, for public electricity and heat production, as shown in Europe and the United States (EEA 2007; EIA 2007).

Despite the above-mentioned limitations and difficulties in projecting other variables, such as population growth, economic development, energy use, and production, climate has the potential of inducing an increased concentration of all air pollutants, PM, and ozone in particular. However, there is a possibility of a decrease in demand of heating systems during milder winters. Hopefully, measures aimed at reducing air emissions of air pollutants will contribute to mitigate the negative effects.

1.09.4.2 Possible Effects on Airborne Allergens

Weather variables, mainly air temperature, sunlight, and rainfall, together with CO_2, are among the main factors affecting phenology (i.e., the times of the appearance of first leaves, first flowers, autumn leaf coloration, and so on) and, mostly important from an allergological point of view, pollen production per plant. In addition, weather patterns influence the movement and dispersion of all aeroallergens in the atmosphere through the action of wind and rainfall and depending on the atmospheric stability.

Current data suggest that there are changes in duration, intensity, and start of the pollen season, even though substantial differences are observed among taxa, species, and

Table 2 Possible changes in airborne allergenic pollen levels and allergenic plants distribution in Europe

Examples of possible effects of climate in the coming decades	*Pollen involved*
Earlier start of pollen season (western and Baltic Europe)	Mugworth, pellittory, grass, birch
Extended duration of pollen season	Summer and late flowering species
Increase of long distance episodes	Ragweed, birch
Increased pollen allergenicity	Ragweed
Increased pollen production	Ragweed, birch

geoclimatic areas (Table 2). However, the extent of evidence varies from one to the other. A number of studies indicate a clear association between climate and significant advances in spring flowering times with subsequent shifts in plant phenology (Fitter and Fitter 2002; Cleland et al. 2007). The availability of extensive time series of pollen count in the air and field phenological observations in Europe provided an impressive amount of data on these possible changes in allergenic plants. Preliminary studies performed in other continents confirmed these findings (Levetin & Van de Water 2008).

Pollen allergenicity is associated with allergen concentrations. Some experimental and field studies report an increase in allergen content of pollen produced by plants growing in higher temperatures and in CO_2-enriched atmosphere (Ziska and Beggs 2012).

The concentration of Amb a 1, ragweed's major allergen, in protein extracted from the pollen of *A. artemisiifolia*, increases in a CO_2-enriched atmosphere (of which the levels were selected based on expected anthropogenic emissions in the coming decades) (Singer et al. 2005). However, in a field study, a significantly higher quantity of antigenic protein was extracted from pollen at the rural site (a low-CO_2 area) relative to an urban site (a high-CO_2 area), despite the fact that in the urban site, pollen production was significantly higher (Ziska et al. 2003). Similar findings have been published about the effects of higher temperature on pollen production and allergen content of the major allergen, Bet v 1 (Ahlholm et al. 1998). Recent studies show that the allergen content of pollen of birch (Buters et al. 2010), pellittory (Jato et al. 2010), and olive trees (Moreno-Grau et al. 2006) vary with location, year of collection, and cultivars, suggesting that the variation of allergen content is affected by several environmental and genetic factors.

Nearly all species and regions analyzed have shown significant changes in seasonal onset that are coincident geographically with an increase in temperature (Cecchi et al. 2010). However, in some cases, local climatic conditions played an important role. For example, data provided by the International Phenological Gardens network showed that spring events advanced by 6 days, the highest rate of phenological changes being observed in Western Europe and the Baltic regions (Menzel and Fabian 1999). Conversely, phenological trends appear to be different in eastern parts of Europe, sometimes showing a 1- to 2-week delayed onset of the phases (Ahas et al. 2002). Duration of the pollen season is also extended, especially in summer and in late flowering species (Frei and Gassner 2008).

Urban areas provide an interesting model for analyzing the effect of an increase in air temperature and CO_2 concentrations. Some preliminary results show an earlier start of flowering in urban compared to rural areas, for example, *Ambrosia* (Ziska et al. 2003) and *Platanus acerifolia* (Mimet et al. 2009). Experimental data support the above-mentioned observations, as indicated by a meta-analysis to assess the effects of CO_2 enrichment (500–800 ppm) on reproductive organs, showing that total plant mass increased by 31% under elevated CO_2 concentrations compared with controls (Jablonski et al. 2002), and in experimental studies on *A. artemisiifolia* (ragweed) in which both pollen production (Rogers et al. 2006) and floral spikes per plant were increased when CO_2 levels are elevated (Wayne et al. 2002).

Increases in temperature are also inducing an altitudinal and longitudinal plant migration (Cecchi et al. 2010), thus changing plant species diversity and density, and then provoking habitat alteration or fragmentation. These changes could expose allergic population to new allergens. As an example, pollen data from the National Allergy Bureau in the United States and the Aerobiology Research Laboratories in Canada demonstrated that the duration of the ragweed pollen season has been increasing with the increase of latitude (Ziska et al. 2011). However, additional factors are accelerating the migration of this invasive allergenic plant. For example, in the eastern European countries, the expansion of ragweed seems also to be associated with major socioeconomic transitions that occurred during the inception and collapse of communism, which contributed to increased areas of disturbed land (suitable for ragweed proliferation) (Kiss and Béres 2007). A northward shift of distribution of birch, olive trees, and ragweed and a corresponding increase in height of the altitudinal tree line have been projected by Emberlin (1994).

Trends of grass pollen are more heterogeneous, possibly because of the numerous species that contribute to pollen counts in the different countries. In general, warming and increased CO_2 concentrations are thought to favor a northward expansion of some species of grasses (Olesen and Bindi 2002). However, a two-phase trend in the 38-year pollen dataset of Basel, with a decreasing pollen count for grass and birch in the period 1991–2007, has been shown by Frei and Gassner (2008). A declining trend is also reported for yearly Poaceae pollen counts in Leiden (the Netherlands) (Jäger et al. 1991), in London and Derby (United Kingdom) (Emberlin et al. 1993, 1999), in Parma (Italy) (Ridolo et al. 2006), and, even with a smaller dataset, in two Spanish studies (Gonzalez Minero et al. 1998; Jato et al. 2009).

Damp housing has been related to asthma in both children and adults, potentially with a high economic impact. Evidence from epidemiologic studies and meta-analyses showed indoor dampness and mold to be associated consistently with an increase in asthma prevalence and exacerbation, current and ever diagnosis of asthma, wheeze, and allergic rhinitis (Mendell et al. 2011). Associations were found in allergic and nonallergic individuals. Evidence strongly suggested causation of asthma exacerbation in children. Although a role for allergic sensitization associated with fungal exposure is plausible, the

evidence is less strong than in the case of asthma and rhinitis. The potential for exposure to other bioactive molecules associated with dampness, such as endotoxins, volatile organic compounds, and mycotoxins, may also be relevant.

1.09.5 Case Study: 'Thunderstorm Asthma'

Since the first report in 1985 (Packe and Ayres 1985), several episodes of outbreaks of asthma, with a significant increase in emergency room visits and some cases of near-fatal asthma, were associated with thunderstorms in several parts of the world (Bellomo et al. 1995; Marks et al.; Venables et al. 1997; Girgis et al. 2000; Wardman et al. 2002; D'Amato et al. in press). Mechanisms underlying the so-called 'thunderstorm asthma' are still unclear. Studies published so far support the hypothesis that several mechanisms come into play. Weather conditions such as rain or humidity may induce fragmentation of pollen grains, which releases allergenic biological aerosols into the atmosphere (D'Amato et al. 2007) Grass pollen and spores are the aeroallergens mostly involved in thunderstorm asthma episodes reported so far (Pulimood et al. 2007), but other pollen types could act as triggers of these outbreaks (D'Amato et al. 2008). Pollen involvement has been objectively shown in an Australian study with the arrival of a thunderstorm outflow accompanied by a large increase in the concentration of ruptured pollen grains in ambient air, thus concentrating pollen grains at ground level (Marks et al., 2001).

Heavy rainfall episodes, including thunderstorm, may increase in terms of intensity and frequency in the next decades, which may increase gradually the number and severity of asthma attacks both in adults and children (Solomon et al. 2007). Even if thunderstorm asthma outbreaks usually involve a small number of patients, asthma attacks are often severe and sometimes near fatal. The public health impact of thunderstorm-related asthma may be not be negligible. To this regard, it might be considered as a useful case study of possible future risks for the population related to possible changes in regional and local climate and of possible adaptation strategies to reduce those risks.

1.09.5.1 Adaptation Strategies

In the case of thunderstorm asthma, adaptation strategies should essentially be based on a warning system.

The setup of a thunderstorm watch/warning system for an asthmatic population (Figure 1) involves the following:

1. *Selection of 'at-risk' countries, that is, those countries with a high prevalence of asthma and high risk of thunderstorms*. Presence of certain types of pollen (grass, pellittory, and olive tree) and spores has been shown to increase the risk of asthma outbreaks during a thunderstorm. Scientific literature indicates Europe (mainly Italy and United Kingdom) and Australia as the more at-risk areas of the world.
2. *Implementation of a weather service with a thunderstorm warning system*. A focused warning system should be able to

forecast thunderstorms, possibly indicating the risk of occurrence of an extreme event, for example, expressed as a percentage of risk, like in the case of rainfall.

3. *Identification of at-risk populations*. Subjects with asthma and known sensitization to one or more of the 'culprit' pollen and spores represent the more at-risk population and should be considered the main target of a warning system. As subjects with allergic rhinitis and without previous asthma may experience severe bronchoconstriction, they should also be included. Asthmatics who have already experienced severe asthma attacks are possibly at higher risk, as recently described by D'Amato et al. 2012.
4. *Measures aimed at reducing the risk of asthma attacks*. At-risk subjects should be advised to stay indoors and to close the windows when a thunderstorm is approaching. As previous studies have shown an increase of severe asthma attacks among poorly controlled subjects, they should be provided with a plan of treatment, including a step-up in the treatment and rescue therapy.
5. *Dissemination of information*. When a defined threshold of risk of a thunderstorm is forecasted, the population at risk is alerted via broadcasts, text messages, and e-mail. Emergency rooms are also alerted and prepared for a possible increase of life-threatening asthma attacks.

1.09.6 Conclusions

Possible effects of climate on prevalence and exacerbations of allergic respiratory diseases are complex and difficult to be projected. The reason behind this uncertainty is the complexity of environmental factors that play a role in the etiopathogenesis of both rhinitis and asthma. Among these factors are airborne allergens and pollutants, even interacting at different levels and affected by meteorological conditions that influence their concentration in the air. Climate factors affect all the processes of production, dispersion, and diffusion of pollen and atmospheric concentration of pollutants. Almost all studies published so far indicate that local conditions are of great importance, making predictions more difficult.

In summary, current knowledge suggests a potential negative effect of climate in the coming decades on the environmental factors involved in the mechanisms of development and exacerbations of allergic respiratory diseases. To this regard, the so-called 'thunderstorm asthma' can represent a useful model of an extreme event with public health implications. Even if currently rare, these events may increase in some areas of the world in the next decades; so, adaptation strategies are needed in order to reduce the number and severity of asthma attacks.

1.10.1 Precipitation and Flood Risk

Floods are the most frequent natural disasters, and have caused over 200 000 deaths and affected over 2.8 billion people over the last 30 years (Centre for Research on the Epidemiology of Disasters). The most common cause of flooding is long-lasting or intense heavy rainfall, resulting in high river runoff (Few et al. 2004). Rainfall over a long period may cause a gradual rise in river levels that can result in the overflow of rivers and inundation of surrounding areas. Intense rain from storms and cyclones, on the other hand, may cause rapid runoff and sudden flash floods across river basins. Floods can also be caused by tidal and wave extremes such as storm surges or tsunamis, the thawing of ice or structural failures such as breaches of dams or sea defenses (Few et al. 2004).

Reports indicate that floods may be intensifying and that this trend could continue in the future (Easterling et al. 2000; Milly et al. 2002). Regional changes in precipitation characteristics (e.g., total amount, variability, and frequency of extremes) have been suggested to increase the frequency and intensity of floods (Watson et al. 1997). The effects of floods on population health may be of significant concern.

1.10.2 Health Impacts of Floods and High Rainfall

1.10.2.1 Diarrhea

Increased transmission of diarrheal diseases is possible during flood and postflood conditions. In high-income countries, the risk of diarrhea due to flooding is considered to be low (Hunter 2003; Ahern et al. 2005), although a study in the United Kingdom reported an increased risk of gastroenteritis for flood-exposed individuals (Reacher et al. 2004). A cohort study performed in the United States found that house or yard flooding was associated with an increased risk of gastrointestinal illness (Wade et al. 2004). Self-reported diarrhea was used as an outcome measure in these two studies.

In low-income countries, where water supply, sanitation systems, and the causative agents of diarrhea are likely different from those in high-income countries, postflood increases in cholera (Sur et al. 2000), rotavirus (Ahmed et al. 1991; Fun et al. 1991), cryptosporidiosis (Katsumata et al. 1998), and nonspecific diarrhea (Woodruff et al. 1990; Siddique et al. 1991; Biswas et al. 1999; Mondal et al. 2001; Kondo et al. 2002; Kunii et al. 2002) have been documented. In one instance, an area outside a flood-control embankment had an 18% higher mortality rate compared with the rate inside the embankment, suggesting an adverse effect of flooding on diarrheal mortality (Ali et al. 2002). A study of a diarrheal epidemic during floods in Bangladesh provided good evidence for an increase in diarrheal cases due to some pathogens (Schwartz et al. 2006). During three consecutive flood-related epidemics in 1988, 1998, and 2004, the mean number of cases due to *Vibrio cholerae*, *Shigella*, *Salmonella*, *Entamoeba histolytica*, *Giardia lamblia*, and rotavirus increased compared with seasonally matched nonflood periods. *Vibrio cholerae* played a primary role in flood-related epidemics, because it was the only pathogen with an increased proportion of cases during the flood compared with the nonflood period. Schwartz et al. also reported that the cases during flood-related epidemics were older and of lower socioeconomic status than those in nonflood periods.

An episode analysis of the 1998 flood in Bangladesh revealed that during the flood, the number of noncholera diarrhea cases was almost two times higher than expected, while the number of cholera cases was almost six times higher than expected (Hashizume et al. 2008a, 2008b). In the postflood period, the risk of noncholera diarrhea was significantly higher for those with a lower educational level, who lived in a household with a nonconcrete roof, who drank tube-well water (versus tap water), or who used a distant water source or unsanitary toilets. These results suggest that those with low

http://dx.doi.org/10.1016/B978-0-12-384703-4.00117-9

socioeconomic status and/or poor hygiene and sanitation were most vulnerable to flood-related diarrhea. The risk of cholera was significantly higher for those drinking tube-well water and those using unsanitary toilets. Another study also reported that populations with poorer hygiene and sanitation or lower socioeconomic status had a greater risk for diarrhea (Kunii et al. 2002).

Floods adversely affect water sources and supply systems, as well as sewage and waste disposal systems (Parker and Thompson 2000). For example, the waste disposal system in Dhaka was almost completely ineffective during the major flood of 1998 (Nishat et al. 2000), and a number of tube-wells were covered by floodwaters and contaminated (Rashid 2000). Many flood-affected people were displaced and took refuge in temporary shelters (Karim et al. 1999). Some of the shelters were extremely crowded (Karim et al. 1999), and deteriorated environmental conditions were observed in shelters and slums (Ahmed et al. 1999). These observations imply that hygiene and sanitation practices in the city were extremely disrupted, and it is likely that the transmission of enteric pathogens increased during the flood.

The effects of flooding on diarrheal incidence tend to fall disproportionately on individuals at socioeconomic disadvantage and those with poor hygiene and sanitation practices. Public health measures to prevent or reduce the burden of diarrhea in these vulnerable populations (e.g., provision of clean potable water and sanitary toilets, hygiene and sanitation education, and temporary measures to reduce pathogen concentrations in drinking water such as chlorine tablets and using a sari cloth as a filter) must be stressed during a response to flooding. These strategies may also be important measures in adapting to a future climate (World Health Organization 2003a, 2003b).

Many studies have reported a seasonal coincidence of peak diarrhea incidence with the rainy season in tropical regions (Cairncross and Feachen 1993). For example, a cohort study with daily surveillance for 1 year in rural Thailand showed that both dysentery and watery diarrhea rates peaked during the early rainy season (Sutra et al. 1990). In another rural Thailand study, a high incidence of acute diarrhea occurred at the beginning of the rainy season (Pinfold et al. 1991). However, these observational studies did not address a direct association between rainfall and diarrhea, meaning that calendar time effects (e.g., long-term trends and season) could potentially confound the results.

A study of 548 outbreaks recorded from 1948 to 1994 in the United States reported a relationship between outbreaks of waterborne diseases and heavy rainfall events (Curriero et al. 2001). Fifty-one percent of waterborne disease outbreaks were preceded by extreme rainfall events. The analysis stratified by water contamination source, and showed the strongest association between outbreaks due to surface water contamination and extreme precipitation during the month of the outbreak. This finding suggests that the route of exposure was ingestion of contaminated drinking water, which was likely contaminated by flooding or rainfall.

Only a few studies quantify the relationship between rainfall and diarrhea while allowing for potential confounding by temperature and calendar time effects. A time-series study in Fiji reported that high rainfall was associated with significant increases in diarrhea in the same month, but decreased diarrhea in the following month (Singh et al. 2001). After allowing for the effects of long-term trends and seasonal patterns, the reported incidence of diarrhea increased by 2% (95% confidence interval (CI): 1.5, 2.3) for each $1\ \mathrm{kg\,m^{-2}\,min^{-1}}$ increase in rainfall above the median value and by 8% (95% CI: 7.6, 9.2) for each $1\ \mathrm{kg\,m^{-2}\,min^{-1}}$ decrease in rainfall below the median. The authors suggested that high rainfall initially flushes fecal contaminants from pastures and dwellings into water supplies, but that continued rainfall could lead to a subsequent improvement in water quality.

1.10.2.1.1 Cholera

Cholera dynamics in endemic regions show regular seasonal cycles. An annual bimodal distribution is observed in Bangladesh (Pascual et al. 2002), while annual single peaks are seen in South America (Codeco 2001), India (Jesudason et al. 2000), and Pakistan (Sheikh et al. 1997). This clear seasonality suggests that weather factors play a role, either directly or indirectly through intermediate pathways. However, little empirical evidence of the role of these weather factors has been presented.

Glass et al. (1982) investigated the relationship between cholera peaks and monthly river level, temperature and rainfall using historical data from 1966 to 1988 in Matlab, Bangladesh. They found a cholera peak in the postmonsoon season and a smaller peak before the monsoon season, and reported that "variations in the time of onset, time to peak incidence, or time of maximum rise and fall in the number of cholera cases could not be forecast by changes in the timing of environmental parameters such as peak rainfall or onset of the monsoon, high and low river water levels, or rise and fall in the mean peak or low monthly temperature".

Pascual et al. (2002) suggested that high rainfall during the monsoon season in Bangladesh could reduce cholera cases by diluting the concentration of *V. cholerae* in aquatic environments and reducing the salinity levels of surface water below the optimum requirements for *V. cholerae* survival. This hypothesis was inferred from the observation of a marked depression in cholera incidence during the monsoon season. In contrast, cholera peaked during the monsoon season in dryer areas of India (Pascual et al. 2002). The incidence of cholera is influenced by primary transmission of *V. cholerae* from an aquatic environmental reservoir in endemic regions (Lipp et al. 2002), and a variety of physical and biological parameters are likely to influence the growth and survival of *V. cholerae* in the environment (Faruque et al. 2005a, 2005b). The effect of rainfall on the seasonality of cholera may depend on average rainfall levels (Pascual et al. 2002).

Cockburn and Cassanos (1960) proposed that ponds in Bangladesh were the main sources of infection in the community, hypothesizing that if the pH in the ponds were sufficiently elevated, *V. cholerae* could have a survival advantage over other bacteria. They showed a relationship between elevated pH and the onset of cholera cases, which was also related to season, sunlight, temperature, and rainfall. In this hypothesis, algae sequestration of CO_2 during photosynthesis drove the temporal pH changes. The largest pH changes occurred with elevated temperatures, low turbidity, and sufficient light. According to the Cockburn and Cassanos hypothesis, when high rainfall muddies and dilutes pond water the pH will not rise, and *V. cholerae* will lose its survival advantage.

Lipp et al. (2002) proposed a cholera model of hierarchy consisting of abiotic factors, phytoplankton and aquatic plants, zooplankton and transmission to humans. *Vibrio cholerae* growth rates increase in aquatic environments at warm temperatures in combination with high pH conditions and blooms of phytoplankton, aquatic plants, or algae. Sunlight, temperature, and nutrients in the aquatic environment influence the growth of phytoplankton and aquatic plants that in turn alter the dissolved O_2 and CO_2 content of the water, changing the pH of the surrounding water. High phytoplankton production produces food for zooplankton, to which *V. cholerae* attaches for protection from the external environment and proliferates.

A time-series study using hospital surveillance data in Bangladesh reported that for a 10 mm increase above a threshold of 45 mm in average rainfall over current and previous 8 weeks, the weekly number of cholera cases increased by 14% (Hashizume et al. 2008a, 2008b). Conversely, the number of cholera cases increased by 24% for a 10 mm decrease below the same threshold of average rainfall over the current and previous 16 weeks. River levels partly explained the association between high rainfall and the number of cholera cases; after controlling for seasonal and between-year variations and rainfall, the number of cholera cases increased by 137% for a 1 m increase in average river level above a threshold of 4 m over current and previous 4 weeks.

Phage predation of *V. cholerae* has also been reported as a possible factor influencing seasonal cholera epidemics in Bangladesh. Faruque et al. suggested that epidemics would most likely begin in periods of low phage concentration (e.g., after floods and the monsoon season). This suggestion stemmed from the observation of an inverse correlation between the environmental concentration of vibriophages and the presence of susceptible *V. cholerae* strains in water (Faruque et al. 2005a, 2005b). The authors also proposed that phages play a predominant role in ending cholera epidemics, although a recent simulation study did not support this hypothesis (King et al. 2008). More research on phage concentrations and cholera epidemics is needed to confirm or deny the phage predation hypothesis.

Huq et al. (2005) reported a time-series analysis using clinical and environmental data (including water temperature, air temperature, water depth, rainfall, pH, salinity, water conductivity, dissolved O_2, bacteria, and copepod counts in water samples) collected at biweekly intervals in four rural locations in Bangladesh for 4 years. They found a significant negative association between rainfall and cholera incidence in some locations, with different lags of 0–8 weeks.

Apart from seasonality, cholera dynamics in endemic regions also show marked interannual variability. In the analysis of historical data from former British India, rainfall was associated with cholera's spatial distribution (Pascual et al. 2002). Average annual cholera mortality in nine provinces of former British India was higher in provinces with higher annual rainfall.

Koelle et al. (2005) reported environmental determinants of interannual cholera cycles in rural Bangladesh while taking intrinsic host immunity into account. The interannual variability of cholera showed a strong inverse relationship with monsoon rains and Brahmaputra River discharge over long periods of time (over 7 years), Conversely, the interannual variability of cholera showed a positive relationship with flood extent in Bangladesh, sea surface temperatures in the Bay of Bengal, and the El Niño Southern Oscillation (ENSO) over shorter periods of time (less than 7 years). The authors suggested that understanding the interannual cycles of cholera requires a combined analysis of both environmental and intrinsic host factors.

In summary, high rainfall is likely to influence the growth, survival, and proliferation of *V. cholerae* in aquatic environments through a complex interaction of factors including temperature, sunlight, salinity, pH, phytoplankton, and zooplankton in the aquatic environment. From the observation of a reduction in cholera incidence during the monsoon season in Bangladesh, high rainfall has been suggested to reduce cholera cases by diluting *V. cholerae* and by reducing water salinity levels below the requirements for pathogen survival. In the analyses of interannual cholera variability, rainfall, particularly in the monsoon season, is suggested to be negatively associated with cholera incidence at longer lags. However, there is little epidemiological evidence for a seasonal influence of rainfall on cholera incidence that also takes seasonally varying factors into account.

1.10.2.1.2 Cryptosporidiosis

A number of outbreak investigations of cryptosporidiosis in the United Kingdom and the United States have suggested that a contributing factor in the outbreaks was drinking or recreational water contamination by heavy rainfall. In a 1993 cryptosporidiosis outbreak in Milwaukee, more than 400 000 people were estimated to have developed symptomatic gastrointestinal infections (Mac Kenzie et al. 1994), although this number has been criticized as a 10-fold overestimation (Hunter and Syed 2001). Outbreak investigations in Ayrshire, Scotland, concluded that irregular seepage of oocyst-containing water increased during heavy rains and was the cause of the waterborne outbreak through water tank contamination (Smith et al. 1989). In an outbreak in Warrington, England, cases were strongly associated with drinking unboiled tap water from contaminated sources (Bridgman et al. 1995). In this outbreak, one water source was found to drain surface water directly from a field containing livestock feces. Similarly, an outbreak investigation in Bradford, England, reported that heavy rainfall was recorded in the catchment area of the reservoir supplying raw water to the water treatment facility immediately prior to the probable time of infection (Atherton et al. 1995). Outbreaks associated with recreational use of contaminated rainwater runoff have also been reported in New Jersey, the United States (Kramer et al. 1998).

Seasonal patterns of cryptosporidiosis vary from country to country. In temperate regions, the peak incidence of cryptosporidiosis is seen in spring to early autumn. In the United Kingdom, seasonal peaks of cryptosporidiosis have occurred in both spring and autumn (Public Health Laboratory Service Study Group 1990). In North America, peak incidence occurs in summer and early autumn (Sorvillo et al. 1998; Dietz et al. 2000; Naumova et al. 2000; Hlavsa et al. 2005; Laupland and

Church 2005). In tropical regions, the seasonal peaks often coincide with periods of high rainfall. A hospital-based study conducted in an urban setting in Gambia reported that peak prevalence of *Cryptosporidium*-associated diarrhea were recorded during rainy months, while no case was recorded during dry months (Adegbola et al. 1994). Similarly, a 4-year cohort study of children born in an urban slum in Brazil showed that the percentage of *Cryptosporidium*-associated diarrhea ranged from 16.4% during the rainiest month of the year to 0% during 4 of the 5 driest months of the year (Newman et al. 1999). In these studies, rainfall exacerbation of low-level water source contamination was suggested as a cause of seasonal peaks during the rainy season. The pattern of the highest number of cases occurring during rainy months has been observed in other tropical countries, including Bangladesh (Rahman et al. 1990), India (Nath et al. 1999; Gambhir et al. 2003), Indonesia (Katsumata et al. 1998), Uganda (Tumwine et al. 2003), and Guatemala (Bern et al. 2000). However, these studies did not control for season, so it is possible that rainfall is a marker for other environmental or behavioral factors that are more often observed in rainy seasons. Seasonal patterns of cryptosporidiosis may also indirectly reflect the interaction of rainfall with agricultural events such as the application of animal and human excreta to pasture as fertilizer (Casemore 1990; Meinhardt et al. 1996).

Lake et al. (2005) conducted a time-series analysis of the relationship between the monthly cryptosporidiosis rate and weather and river flow in England and Wales allowing for seasonal effects. Between April and July, the period when many newborn animals are on the land, the cryptosporidiosis rate was positively associated with river flow in the same month, after controlling for seasonal variations, rainfall and temperature. The authors suggested that high water saturation of the land during this season might be related to the efficient transportation of *Cryptosporidium* into river water by runoff. However, from August to November, warm and dry weather during the previous month was associated with cryptosporidiosis rates, and the authors hypothesized that *Cryptosporidium* falling onto the dry soil likely builds up and is effectively transferred by runoff into river water.

Naumova et al. (2005) reported a time-series analysis of the relationship between the weekly cryptosporidiosis rate and precipitation in northwestern England. After controlling for seasonal variations, the weekly cryptosporidiosis rate increased by 27% (95% CI: 21, 33) if the cumulative rainfall for the prior week was at the 75th percentile.

In summary, there is a clear link between high rainfall events and outbreaks of cryptosporidiosis through drinking or recreational water contamination. Seasonal cryptosporidiosis peaks and high rainfall periods coincide in tropical regions. This could be because of water source contamination by rainfall, but few of these studies have adjusted for seasonal variations. Only a few studies in the United Kingdom have measured rainfall effects on the incidence of cryptosporidiosis while allowing for seasonal variations.

1.10.2.1.3 Other Pathogens

The largest reported outbreak of *Escherichia coli* O157:H7 in the United States occurred in the State of New York in September 1999 and was linked to contaminated well water (Rose et al. 2001). Unusually heavy rainfall preceded by a drought coincided with this major outbreak. High soil saturation with water leading to the rapid transport of microbial agents was suggested as a factor that contributed to the well water contamination.

A large outbreak of bloody diarrhea caused by *E. coli* O157 infections in South Africa was reported in relation to heavy rainfall (Effler et al. 2001). Carriage of *E. coli* O157 by cattle, cattle deaths due to drought, and subsequent heavy rains that contaminated surface water were suggested as important factors contributing to the emergence of *E. coli* O157 in the region.

Shigella infections were found during the months of highest rainfall in the Philippines (Adkins et al. 1987). In contrast, shigellosis was more frequent during the cool, dry months in Bangladesh (Black et al. 1982; Stoll et al. 1982) and during hot, dry months in Israel (Vasilev et al. 2004). For *Salmonella*, a study in Guam showed that monthly rainfall was positively associated with the number of cases, especially in infants (Haddock and Malilay 1986). However, season was not adjusted in this study, so the rainfall could have been a marker for other environmental factors observed during the rainy season. Current knowledge is insufficient to make solid conclusions about the relationship between rainfall and Shigella, or between rainfall and Salmonella.

Outbreaks of other pathogens in private drinking water supplies have been reported in England and Wales (Said et al. 2003). Heavy rainfall was identified as a factor implicated with 4/25 outbreaks through 1970–2000. Two of these were attributed to *Campylobacter*, one to *Giardia*, and one to a mixture of *Cryptosporidium* and *Campylobacter*.

1.10.2.2 Acute Respiratory Infections

Acute respiratory infection (ARI) is a major cause of illness and death among populations displaced by natural disasters, particularly in children under 5 years of age (Watson et al. 2007). Lack of access to health care facilities and antimicrobial agents for treatment further increases the risk for ARI mortality. Risk factors among displaced populations include crowding, exposure to indoor cooking using an open flame, and poor nutrition. The reported incidence of ARI increased fourfold in Nicaragua in the 30 days after Hurricane Mitch in 1998 (Campanella 1999), and ARI was the most common cause of disease and deaths among those displaced by the 2004 Aceh tsunami (World Health Organization 2005). In Bangladesh, respiratory problems (14%) were the second highest cause of illness among those affected by flooding in 1998, following diarrhea (27%) (Kunii et al. 2002). ARI was also the second most common cause of illness (17%) and death (13%) among those affected by the 1988 flood in Bangladesh (Siddique et al. 1991). However, it is not clear whether the high number of ARI was caused by the flood or by a usual seasonal increase. Rigorous studies on the effect of flooding on ARI incidence are warranted.

1.10.2.3 Malaria

Rainfall is a major contributing factor to the increase of malaria cases (Kilian et al. 1999; Zhou et al. 2004; Thomson et al. 2005; Abeku 2007). In Ethiopia, higher rainfall was associated with increased malaria cases with saturating effects at higher rainfall levels. The association has been shown to have a shorter lag time in hot districts than in cold districts (Teklehaimanot et al. 2004). In Zimbabwe, rainfall and maximum temperature at a lag of 4 months fit a biological transmission model to malaria case data (Worrall et al. 2007). Malaria cases increased by 1.4%–10.7% per month for each 10 mm increase in monthly rainfall (with a 2–3 month lag) in the highlands of West Kenya (Hashizume et al. 2009). In contrast, interannual analysis of long-term data from Sri Lanka (1972–2005) showed negative correlations between malaria cases and rainfall in the districts with high annual rainfall (Briet et al. 2008). Meanwhile, no clear relationship was observed between rainfall and malaria incidence in central India (Singh and Sharma 2002).

Postflood increases of malaria transmission have been reported from Africa, Asia, and Latin America. For example, sharp increases in the number of malaria cases after 1982 El Niño-related flooding were reported in Latin American countries (Moreira Cedeno 1986; Russac 1986; Heddera 1987), and the number of malaria cases increased 1.5–2-fold following flooding in Mozambique in 2000 (Kondo et al. 2002).

Floods may also lead to geographical changes in malaria epidemic areas by changing breeding sites for vector mosquitoes. An epidemic of malaria was associated with changes in habitat following flooding in Costa Rica (Saenz et al. 1995). Malaria epidemics can also occur when people with little immunity move into endemic areas, although the displacement of large populations has rarely occurred as a result of acute natural disasters (Toole 1997).

1.10.2.4 Dengue Fever

High rainfall has been associated with dengue in Barbados (Depradine and Lovell 2004), Indonesia (Corwin et al. 2001), Mexico (Chowell and Sanchez 2006), Puerto Rico (Johansson et al. 2009), Taiwan (Chen et al. 2010), Thailand (Wiwanitkit 2006), Trinidad (Chadee et al. 2007), and Venezuela (Barrera et al. 2002). Floods can potentially increase the transmission of dengue. Standing waters caused by the overflow of rivers can act as breeding sites for mosquitoes, enhancing the potential for exposure of flood-affected populations to dengue (World Health Organization 2004). However, few studies have reported an association of dengue epidemics with flooding. No dengue infections were reported among relief workers in Puerto Rico after Hurricane George (1998) (O'Leary et al. 2002; Rigau-Perez et al. 2002), no outbreaks of dengue occurred after Hurricane Jeanne (2004) in Haiti (Beatty et al. 2007), and a low incidence of dengue was reported in flood-affected areas of Malaysia (Shaharom et al. 2009). After flooding in Thailand, an increase in the number of acute pyrexia cases was reported, of which 29% were dengue and 27% were leptospirosis (Pradutkanchana et al. 2003).

Hashizume et al. (2012) found a significant association between hospital visits for dengue and high river levels with a shorter lag time (0–5 weeks), and between hospital visit for dengue and low river levels with a longer lag time (6–19 weeks) in Dhaka, Bangladesh. The number of dengue cases increased when a prolonged low river level preceded a high river level. This result is consistent with a report that the number of dengue cases was higher when prolonged drought preceded the rainy season (Gagnon et al. 2001).

Although rainfall may increase the number of water containers available for mosquito breeding and lead to increased larval habitat, and vector population size (World Health Organization 2003a, 2003b), heavy rainfall may reduce mosquito numbers by destroying existing breeding sites and inhibiting the development of mosquito eggs or larvae (Patz et al. 1998). Additionally, differences in local water container types and water storage practices of the local population may lead to variations in the association between rainfall and *Aedes* mosquito abundance (Jansen and Beebe 2010).

1.10.2.5 Other Infectious Diseases

High rainfall and flooding increase the risk of leptospirosis by bringing the bacterial pathogen *Leptospira interrogans* and its animal hosts (e.g., rodents, dogs, and cats) into closer contact with humans. There have been reports of flood-associated outbreaks around the world including in the Philippines (Amilasan et al. 2012), India, Brazil (Ko et al. 1999; Barcellos and Sabroza 2001; Sarkar et al. 2002), Indonesia (Victoriano et al. 2009), Puerto Rico (Sanders et al. 1999), New Caledonia (Goarant et al. 2009), Nicaragua (Ashford et al. 2000), the United States (Gaynor et al. 2007), and Mexico (Sehgal et al. 2002; Leal-Castellanos et al. 2003; Kshirsagar et al. 2006; Bhardwaj et al. 2008).

In Brazil, the monthly number of leptospirosis cases increased by 0.55% per 1 mm increase in maximum daily rainfall of the month (Kupek et al. 2000). In India, peaks of disease onset were preceded by heavy rainfall 7–10 days previously (Pappachan et al. 2004). Periods of heavy rain followed by days of little or no rain were optimal conditions for leptospirosis outbreaks. Brazilian data have shown the presence of a threshold for the association between leptospirosis incidence and rainfall, supporting a hypothesis for the pathway: high rainfall → flooding (overflowing water) → exposure to water contaminated with urine from animals infected with *Leptospira* species (Codeco et al. 2008).

Environmental factors are thought to have been responsible for outbreaks of visceral leishmaniasis (VL) in Sudan in 1985 and 1986, where heavy rains favored sand fly breeding (el-Safi and Peters 1991). Franke et al. (2002) demonstrated a positive relationship between the incidence of VL and the ENSO, which affects rainfall patterns in Brazil. Franke et al. demonstrated that the previous year's mean Niño 3 index and the temporal trend accounted for approximately 50% of the variance in the annual incidence of VL.

Ben-Ahmed et al. (2009) performed a spatial analysis of VL in Tunisia, in association with climatic factors, and identified hot-spot regions of 35 districts located mostly in the semiarid bioclimatic zone. The incidence of VL was positively correlated with mean yearly rainfall and continentality index (difference between mean extreme values of high-summer and low-winter temperatures). Neronov and Malkhazova (1999) found a significant positive relationship between the incidence of zoonotic cutaneous leishmaniasis (CL) and soil moisture and temperatures in Turkmenistan. Broutet (1994) concluded that epidemics of CL in Brazil between 1986 and 1990 may have been attributable to climatic factors. In addition, the seasonal abundance of sand flies in southwest Asia has been shown to depend on temperature and humidity (Cross and Hyams, 1996; Cross et al. 1996).

Sand fly adults and larvae are sensitive to high temperatures and low humidity. In laboratory experiments, all adult sand flies died within 2 h at temperatures above 40 °C (Theodor 1936). Temperatures below 10 °C are also unfavorable for survival. In addition to temperature, laboratory studies have demonstrated that sand fly survival increases with relative humidity, and that larvae, pupae, and adult sand flies need a habitat with a constant, relatively high-humidity environment (Theodor 1936).

As discussed above, some evidence suggests an association between climatic variability (including events such as ENSO) and the incidence of leishmaniasis. However, climatic variability may have different impacts on the transmission of leishmaniasis in different regions of the world, depending on the particular vectors and the various *Leishmania* species involved.

1.10.2.6 Long-term Effects of Flooding on Mortality and Morbidity

There is little evidence on the long-term health impacts of flooding. A cohort study of people forced from their homes by flooding in 1968 in Bristol, England, found a 50% increase in the number of deaths in the year after the flood among those whose homes had been flooded, compared with people not forced from their homes (Bennet 1970). The number of clinic visits and hospital admissions was also higher in the year after the flood among those who had been affected by flooding compared to those who had not (Bennet 1970). However, an Australian study found no difference in mortality the year after a flood between those who had been affected by flooding and those who had not. However, the authors noted that those who had been affected made a greater number of visits to medical providers (Abrahams et al. 1976). Heightened psychological stress was thought to have played a part in the increase in visits in the two English and Australian studies. A study in England and Wales found a 10% relative reduction in mortality in flooded areas in years after flooding between 1994 and 2005. This finding may be due to the influence of population displacement from flooded areas (Milojevic et al. 2011). Another study in rural Bangladesh found no clear evidence of flood-related increases in mortality or diarrhea during or after the flood period in 2004, once preflood rate differences between flooded and nonflooded areas and seasonality were controlled for in the analyses (Milojevic et al. 2012). A space-time clustering of leukemia and lymphomas was reported in New York after 2 years of major floods in 1972 (Janerich et al. 1981). A study in China also showed higher malignant neoplasm mortality among the residents of flood-affected villages than among those of nonflooded villages in the year after a flood (Li et al. 2007). The standardized years of potential life lost rate for respiratory and circulatory diseases in the flooded village group were also significantly higher than those in the nonflooded village group (Li et al. 2007). The authors speculated that flood-related environmental contamination and psychological and physical stresses after the flood disaster may explain the findings. The long-term effect of floods on stress-related psychological disorders is an important public health issue (Ahern et al. 2005), but the adverse effects of experiencing a flood are not limited to mental health problems. There is clear evidence that chronic psychosocial stress contributes to the pathogenesis and development of coronary artery disease (Rozanski et al. 1999; Kubzansky et al. 2005). However, most of these studies had methodological limitations, in particular, a lack of preflood data, ambiguous exposure measurements, a lack of clinical diagnosis, and potential recall bias. Improved epidemiological research is needed on the long-term health impacts of floods.

1.10.2.7 Chemicals and Mold

There is a concern for potential long-term adverse effects of exposure to chemical contaminants, mold, and other toxic substances that may be present in homes after flood clean-up. A high concentration of mold was measured both indoors and outdoors in the New Orleans area 2 months after the flooding caused by Hurricane Katrina (Solomon et al. 2006). Repeated exposure to significant quantities of fungal material can result in respiratory irritation or allergic sensitivity in some individuals (Bush et al. 2006). There is evidence of a causal link between indoor dampness and upper respiratory tract symptoms, coughs, wheezing, and asthma symptoms in sensitive people (Institute of Medicine 2004).

1.10.2.8 Nutrition

Inadequate nutrition following disruption to incomes and food distribution systems is also important to note (Intergovernmental Panel on Climate Change 2001). There is evidence for an increase in both gastroenteritis and malnutrition during the rainy season in some countries (Draser et al. 1981). This may be associated with changes in food availability, which is lower in the rainy season (Minghelli et al. 1991; Bronson 1995). Higher opportunity costs of time for agricultural work, which is busiest in the rainy season, could disrupt the weaning practices of women (Draser et al. 1981). This could contribute to an increase in infant diarrhea and malnutrition in the rainy season. Long-term low nutritional status of children in flooded households compared to nonflooded households was reported in Bangladesh after the 1998 flood (del Ninno and Lundberg 2005). Fifty-one percent of households in urban areas in Bangladesh suffered income loss due to the flood, which resulted in decreased food consumption in the affected population (Ahmed et al. 1999). Persistent low nutritional in flood-affected populations may be related to the persistence of increased diarrhea incidence. In the presence of malnutrition, chronic or persistent diarrhea could arise secondary to other infections (Thapar and Sanderson 2004).

1.10.3 Health Impacts of Low Rainfall

Low rainfall and drought have been associated with increases in the incidence of diarrhea (Burr et al. 1978). This is particularly relevant where rainwater is collected for household uses. In such areas, hygiene and sanitary conditions seem to be closely related to rainfall (Pinfold et al. 1991). A water source may be utilized for an increasing number of uses during droughts, enhancing the risk of contamination (Lipp et al. 2002).

Increased concentrations of pathogenic agents in raw water supplies are suggested as a possible risk of gastrointestinal infections (Singh et al. 2001). Even where water treatment systems exist, falling water levels and reduced river flows during droughts increase the risk of cyanobacterial blooms, and make water treatment less effective, as levels of sediment and organic material increase (Leder et al. 2002).

The time-series study in Fiji revealed that, after controlling for season, low rainfall was associated with significant increases in diarrhea in the same month and the following month (Singh et al. 2001). Low rainfall was proposed to interrupt water supply and contribute to poor hygiene. Singh et al. also reported a cross-sectional study of the average annual rates of diarrhea and water availability, defined by precipitation per area of countries in the Pacific Islands. There was a negative association between water availability and diarrhea rates; that is, high water availability was associated with lower reported rates of diarrhea.

In temperate regions, rotavirus diarrhea peaks in winter and is rarely seen in summer. In the tropics, the seasonality is less obvious, while peak incidence is reported in cooler months, which often coincides with low rainfall. The peak was in winter, and the trough was in the rainy season in India (Kelkar et al. 1999), Brazil (Rosa et al. 2002), and Costa Rica (Hieber et al. 1978), and in the times of hot, dry weather in Kenya (Mutanda et al. 1984). In the United States, 45% more rotavirus hospitalizations were observed after the months with the least rainfall compared with the months with greatest rainfall (Brandt et al. 1982). Rotavirus outbreaks occurred after a period of prolonged low rainfall in Indonesia (Corwin et al. 2005). Although these findings suggest a seasonal coincidence of peak rotavirus activity with low rainfall periods, they do not provide evidence for a direct association of low rainfall with rotavirus diarrhea allowing for seasonal variations and temperature effects.

In summary, low rainfall has been suggested to increase the incidence of diarrhea through reduced water availability for domestic use and increased concentration of enteric pathogens in raw water supplies. However, few studies have taken into account potential confounding by season and temperature, indicating that further study is needed to determine the relationship between low rainfall and diarrhea.

1.11.1 Introduction

The Ottawa Charter for Health Promotion emphasized that health is not just a state or the object of living but should be considered as a vital resource for everyday life on which numerous services and deliverables depend. Without good health very little is achievable in the life of an individual or collectively in the context of a community (WHO Ottawa Charter 1986). In 1974, Lalonde postulated the early ideas conceptualizing the key determinants of an individual's health as being contingent on the following (Lalonde 1974):

1. The integrity of the human biological system, which includes genetic makeup, cellular senescence, and physiological processes. Aberrations in any of these compartments can result in human illness, pain, and suffering.
2. Healthy environments and ecological integrity. The emphasis on ecological services is paramount to a healthy living milieu for all human communities. These free ecological services represent clean air, fresh water, natural produce, climate stability, food and medicines, restraint on infectious diseases, leisure, and spiritual sanctuaries. These services are priceless; the opportunity cost cannot be valued by any stretch of imagination.
3. Healthy lifestyles. The aggregation of personal decisions (i.e., over which the individual has control) that can be said to contribute to, or cause illness or death. Some individuals may or may not be equipped with adequate information that promote healthy lifestyles, while others may be aware and choose to accept the risks associated with certain activities because they have limited options or are not prepared to forego certain self-indulgences in the interest of preventing illness.
4. Good or adequate health care facilities and policies, which consist of quantity, quality, and accessibility of such resources to the people and which operate at many levels of complexity.

http://dx.doi.org/10.1016/B978-0-12-384703-4.00125-8

National health care strategies tend to place emphasis on conventional hospital-based health care facilities to improve health in communities. When disease burden in a community is high, these strategies can turn out to be economically draining (Harrison 2010b). While these are important, it is evident that majority of the causes of ill health are derived from the first three categories, human biology, environment perturbations, and lifestyle decisions, and are therefore amenable to public health, education awareness, and responsible environmental custodianship. It is argued that the tendency to focus both human and economic resources on category 4 (particularly secondary and tertiary health care facilities), while important, should not proceed at the detriment of preventative strategies incorporating healthy lifestyles and maintaining environmental integrity. This is the key message of the emerging policies for health care coverage for all South Africans, which emphasizes that the high cost of curative hospital centric health care systems are unsustainable into the future, especially in the light of expanding human health epidemics and contracting global economies. The blueprint suggests that more resources and logistics should be funneled into the public health and the primary health care setting (South African Policy Paper on the NHI, DOH 2011). Similar mitigating strategic plans are being promulgated by the South African Department of Environment in the sectors of clean water, quality air, and integral biodiversity (McMichael 2008; Midgley et al. 2008; 2010). These debates are pertinent to the current infectious burden of disease and uncertainty surrounding climatic trends and predictions in the Southern Africa subregion.

In this overview, the phenomenon of human immunodeficiency virus (HIV) infection and acquired immune deficiency syndrome (AIDS) is described in its historical and social context as the harbinger, while tuberculosis (TB), opportunistic infections, chronic inflammation, and specific HIV-related cancers are described as the sequel in a unique and predictable HIV burden of syndemic disease complex. This scenario has gripped South Africa in particular and the rest of the sub-Saharan African continent to varying degrees. The focus in this review is on attempting to put things in spatial, temporal, and relational perspective, elucidating the magnitude and impact of this complex burden of disease sequel as a significant threat to human health and environmental resources in the context of climate. The HIV burden of disease complex has a direct impact on ecosystem integrity and services, which creates an exacerbating cycle of events with feedback loops that perpetuate the epidemic through aggravating vulnerability and impoverishment.

South Africa has an extremely high burden of disease directly related to the emergence of the HIV epidemic in the 1980's, which has progressively escalated in a background of a large sector of the majority ethnic population dependent on subsistence agriculture and historically, geopolitically, and economically marginalized (Harrison 2010b). South Africa has an estimated population of about 55 million and an HIV population prevalence rate of 10%; Statistics South Africa estimates that the number of persons living with HIV (PLWH) is 5.4 million, which equates to 17% of the global burden in a country that contributes to only 0.7% of the world's population. It is suggested that for every person infected with HIV, four other people are affected. This means that 25 million people in South Africa are significantly affected directly or indirectly by the HIV epidemic. Sentinel rates, or the rates seen in the reproductive female population attending antenatal clinics, are on average 30% but can be as high as 47% in some provinces of South Africa. This means that a third to half of the reproductive age group of society are infected with HIV and will get ill eventually and succumb to a predictable HIV-related complication, leaving behind a host of affected dependents and loved ones (National Strategic Plan 2012; DOH; HSRC Annual report 2010/2011).

Embedded in this complex, South Africa is facing one of the worst epidemics of TB, including drug-resistant strains (TB DR-TB), which comprises multi-drug-resistant (MDR-TB) and extensively drug-resistant TB (XDR-TB). With a current per capita TB incidence in excess of 900 per 100 000 population, there has been a more than threefold increase from a decade ago (Lawn et al. 2009, 2011a,b; Middelkoop et al. 2009; Lawn and Zumla 2011; Lawn and Wood 2011). It is clearly understood that HIV and TB have a tandem relationship, and HIV is fueling the growing epidemic of TB in all its forms. Among newly diagnosed HIV patients, basic TB screening tools reveal that more than half have active TB. With more sophisticated technology, this figure is likely to be higher (National Strategic Plan 2012; World TB DOH 10 point plan progress report 2011).

1.11.2 Characteristics of South Africa's History That Lend Itself Favorably to the Spread of HIV and Urban and Rural Environmental Sensitivity

South Africa has a unique history, demographics, economic landscape, diversity of biomes, and complexity of cultures. There are 11 official languages spoken across nine provinces or states (South Africa Information 2012). Its historical legacy based on slavery and segregation created modern cities, farming communities, and a developed world industrial economy in the midst of disenfranchisement effected through forced removals and economic isolation of the indigenous African population over several centuries. The vast mineral wealth of the country created a workforce characterized by huge migrant labor with the consequences of fragmented family units and abnormal congregation of men in remote locations where most mines were located. Simultaneously, domestic city labor force, comprising mainly women, was required to service the affluent, mainly white, European colonial minorities in the cities. This created unplanned townships on the outskirts of major cities, which grew over time into sprawling informal settlements devoid of basic amenities or any form of environmental impact assessments. Movement of this labor force was regulated by strict security and movement laws. These settlements were meant to be temporary but conveniently ignored, and out of necessity they grew in a haphazard and unregulated manner to cater to the domestic and industrial workforce that fed the cities with cheap labor. Several mixed-race communities evolved in the process from the 'illegal' and sometimes forceful fraternization between the colonial land owners and the indigenous populations, slaves from other African countries and Asian indentured workers. Physical and sexual violence coupled with the abuse of alcohol were ingrained in the culture at several levels. The origin of South Africa's reputation as the rape capital of the world is heavily debated in social science forums (Jewkes et al. 2009).

South Africa attained independence in 1994 after a long and protracted violent and cruel resistance movement emanating out of these townships, facilitated by international isolation, eventually creating the opportunity for democratic governance. These historical precedents created perfect conditions that fueled the dramatic spread of HIV infection once introduced into the population. Unfortunately, many of these characteristics still prevail in many forms and guises. Naturally the HIV took off with a vengeance in the disenfranchised majority of the population. While South Africa has a wealthy historical colonially privileged minority subsector and now a new indigenous political elite, there is a rapidly growing middle class comprising previously disadvantaged ethnic groups, mixed and Asian races. However, the majority subsector live in poverty in the rural areas and township settlements in what is described as one of the most unequal economies in the world (New Growth Path Initiative website SA Treasury 2012). South Africa is predominantly a semiarid ecosystem and highly sensitive to changes in rainfall. Attempts to redistribute wealth in a more equitable manner coupled with the high burdens of disease, unpredictable weather pattern trends, and depression of global economies are all coalescing to cause a stagnant economic growth profile characterized by almost insurmountable poverty and inequalities, growing civil unrest, and impatience at what seems to be a slow pace of economic and political reform (Thompson 2001).

1.11.3 Multiple Ramifications of HIV Disease Burden Complex

The impact on communities in countries like South Africa with high numbers of PLWH will be powerful negative social and environmental forces that exacerbate individual and collective vulnerabilities in a number of ways:

1. Loss of individual well-being: PLWH have a weakened natural physiology by virtue of the chronicity and unrelenting attrition of the HIV infection as it wears down the immune system and causes accelerated aging of all structures and tissues, impaired nutrient absorption from the gut, and multiple opportunistic complications on route to a stage defined as AIDS, at which point the individual can be termed as critically unwell and without appropriate intervention will demise in a short period of time. Dramatic deterioration in well-being places a huge strain on households and causes loss of disposable income and livelihood and the tendency for conversion of personal and family assets into cash for subsistence and medical bills. This can be reversed to some extent by the initiation of antiretroviral therapy (ARV) (Bolton and Talman 2010; UNAIDS/WHO 2008; UNAIDS—AIDSinfo Country factsheets 2012).
2. Diversion of gross domestic product (GDP): Countries with high HIV prevalence have increased government spending on health infrastructure, health care providers, and ARV roll out programs, diverting already scarce funds away from other health programs and other state sectors. This places the nation as a whole in a circumstance of fiscal disadvantage and negative economic growth potential (Harrison 2010b). Funds that should be going into alleviation of poverty and attaining other national priority projects like the Millennium Development Goals (MDGs) are being diverted into keeping very sick people reasonably well.
3. Human capital: Depletion of the workforce from ill health (days off sick and death), including caregivers not being able to cope with fulltime jobs or academic activities due to responsibilities for caring for sick family members, contributes to a drain on human capital resource as a national asset and further plunges the family as a unit in deeper states of poverty (Cohen 2002).
4. Collective poverty and migration: Cumulative loss of livelihood and increasing household vulnerability to hunger, loss of assets, and entitlements encourage rural urban migration in search of means of survival and funds to remit back to support family members left in the rural setting, who engage in subsistence farming in increasingly harsh environments. This places added strain on urban informal settlements in particular and all the attended consequences of this trend (Niehof et al. 2010).
5. Dependency on free ecosystem services: As poverty sets in and survival options diminish, households resort to the consumption and utilization of the 'free' natural products derived from the biodiversity habitats in their localities. These are in the form of fuel, food, and medicinal products for personal consumption and/or are traded in exchange for cash or barter (Bolton and Talman 2010; Shackleton and Shackleton 2011).

The consequences of all these have far-reaching ramifications, affecting entire households as the morbidity and mortality from HIV and TB mainly affect the young productive sector of society. In the setting of high prevalence of undernutrition, a superimposing HIV epidemic gives rise to a vicious cycle of food insecurity and worsening health status (Mason et al.; UNEP UNAIDS 2008; UNDP South Africa 2003). There are well-established studies over the decades that prove the chronic impoverishing effects of HIV on communities in Africa, altering livelihoods and spiraling whole communities into deeper poverty traps (Cohen 2002; Niehof et al. 2010; Aliber 2003). Composition and dynamics of families are also drastically affected with more granny-headed or, at the other extreme, orphan-headed households, with high dependency on handouts from relatives and state bursaries (Aliber 2003). The HIV burden of disease complex is a key factor determining human vulnerability and resilience to other shocks and stressors that communities may be exposed to (Shackleton and Shackleton 2011; Gallopin 2006). Elucidating and standardizing the concepts of vulnerability and all its synonyms and antonyms as a science has emerged as a serious and growing area of intellectual enquiry among social scientists, politicians, and environmentalists in light of the Intergovernmental Panel on Climate Change (IPCC), which advocates that anthropogenic-induced environmental changes are going to have serious and far-reaching effects into the next century. The IPCC has stated with claimed confidence in the fourth Assessment Report (Intergovernment Panel on Climate Change 2007) that climatic change is predicted to continue along the lines of the observed trends, with increasing frequencies of both acute catastrophic and insidious events on a global scale. These predictions are made on large-scale geographical dimensions without cognizance of multiple vulnerabilities or coping capacities that exist at the grass roots level that may mitigate or amplify these hazards (Pielke et al. 2011). This is called the top-down approach. Recently, the need to introduce a paradigm shift to incorporate a parallel bottom-up approach has been gaining momentum. This approach proposes to assess the dynamics and interrelatedness of the vulnerabilities, sensitivities, resiliencies, and adaptive capacities that exist at the community level that will determine the cumulative impact, should an external climatic event or other exposure, stressor, shock, or perturbation take place. This approach attempts to identify the coping thresholds and resources of a community beyond which its adaptive and transforming capacity may fail. Furthermore, it also takes into consideration both the human (social) and ecosystems (biophysical) vulnerability coefficients when ascribing risk, of both the acute and chronic changes that may occur (Pielke et al. 2011; Vincent 2004). This chapter will adapt this philosophy in understanding the existing status of individuals and communities in light of one of the major threats to human health and resilience, which is the multiple ramifications of HIV (Niehof et al. 2010) and indirectly the impact that PLWH have on their biophysical environment in South Africa (Shackleton and Shackleton 2011).

Of particular concern for much of the subregion that is mostly dependent on rain-fed and subsistence agriculture is the sociodynamic effect and adaptive capacity to extreme or variable weather patterns such as unpredictable precipitation and warming. This is compounding an already precarious state of food security and worsening the existing state of prevailing undernutrition status of a large sector of the society (Bryan et al. 2009; McGarry and Shackleton 2009).

Such events will aggravate environmental degradation and likely trigger farming techniques and, as in the case of the effect of HIV, increased utilization and dependency on wild and natural resources from their immediate ecohabitats and environments, accelerating biodiversity loss and disturbance of the complexities of ecosystem that ensures Nature's resilience (Shackleton and Shackleton 2011; Scholes and Biggs 2004; Hunter et al. 2007).

1.11.4 Concepts of Vulnerability in the Context of HIV and Climate

The relationship between man and environment is without doubt taking center stage because of the burgeoning population and human footprint. Alongside this are a litany of concepts that define how human systems will deal with climatic perturbations and what the constitutive factors are that define vulnerability and resilience (Scholes and Biggs 2004; Daily and Ehrlich 1995b; Folke 2006).

A healthy socioecological system (SES) is understood as a system that includes the complexity of societal (human) and ecological (biophysical) subsystems in multiple dynamic symbiotic interactions, feedback loops, and interdependencies (Gallopin 2006; Daily and Ehrlich 1995b; Folke 2006). The biophysical can be further divided into the living ecosystem and the physical or the geophysical structure or matrix that houses such a system (Guillaumont and Simonet 2011b). The SES can be examined at several hierarchal levels, ranging from simple microhabitats and progressing to communities, biomes, and ultimately the global system comprising the whole of mankind (anthroposhere interacting with the ecosphere), which form the earth system as we know it (Gallopin 2006).

Human actions are clearly playing an increasingly central role in the inability of the ecosystems to perpetually continue to generate services without which humanity may ultimately cease to exist (Folke 2006). Human governance now more than ever is required to adopt a key leadership role in participating in the environment milieu in such a manner that we must perceive ourselves to be integral rather than external to the healthy functioning of the services that ensure our well-being (Ehrlich and Ehrlich 1992).

With increasing human environmental footprint, greenhouse gases and the ramifications thereof, many attempts are being expounded on how to measure indices of vulnerability, especially in the historically disadvantaged regions of the world that are expected to bear the added brunt of global climate change and variability (Bryan et al. 2009). Understanding how such communities will respond and evolve, especially as the same regions tend to carry a disproportionate share of global stressors in the form of high disease burdens, nontransparent governance, food insecurity, land degradation, and changing market forces, is critical to global justice and social capital.

Consideration of the SES as an indivisible entity emphasizes the integral relationship between modern man's ecological footprint and nature, and any attempts to disaggregate these social and ecological systems would be profoundly flawed. The envisaged 'Adaptation or Green Fund' proposed by the parties to the Kyoto protocol under the United Nations (UN) framework Convention for Climate Change (IPCC), conceived to compensate developing countries for the mitigation expenses and cost of impact, requires some form of objective rational for distribution of the funds equitably and according to vulnerability. In this light, some methods are being proposed to distinguish social and human vulnerabilities from geophysical vulnerabilities of the SES. It is envisaged that such distinction is only necessary to address the complexity and methodology by which these funds can be prioritized and equitably distributed to the most climatically geosensitive countries as a separate entity from the funding earmarked for human development objectives such as the MDGs, which are principally designated for poverty alleviation, the origins of which are deemed to be distinct from climatic perturbation. The logic behind this distinction is based on the fact that the emissions of greenhouse gases are predominantly and historically generated by the industrialized countries and are separate from the exploitative forces that have contributed to the impoverishment of Africa. This distinction, although artificial, has several potential attributes but should be viewed only in the context of the means to which it is being prescribed and not by any stretch of the imagination a suggestion that the social and biophysical entities of an SES are conceivably separable or could function independently of one another or that the genesis of poverty or climatic aberration and environmental desecration can be demarked into clear and distinct precipitating siloes (Guillaumont and Simonet 2011a,b; Ehrlich and Ehrlich 1992; Davies and Krebs 1993; Davies et al. 2011; Daily and Ehrlich 1995a).

The degree to which the SES is affected by exposure to acute or insidious effects from climate variability and possible longer term change in the setting of a high HIV prevalence within the social component of the system requires careful unraveling of complex linkages. In this scenario, climate poses external threat, while HIV pathology and its consequences undermine the SES internally.

The inherent ability of an SES to adjust and respond, also known as its adaptive capacity or resilience, ultimately defines its transforming capacity (Brooks 2003). Such relationships are complex and have multiple inherent components dictated by social and economic dimensions with factors entrenched in cohesive human existence, grass roots, and central governance (Pettengell 2010).

Sensitivity refers to the inherent capacity to preserve and resist change to the behavior and structure of an SES in the face of external or internal perturbation. The degree of sensitivity will determine the impact outcome, while resilience refers to the capacity to recover, which may be short term and referred to as coping or survival, while longer term resilience would have inherent components of adaptation. Transformation may occur in the process of adaptive resilience whereby recovery is associated with beneficial change that may improve the overall sensitivity of the system to further perturbation in the future. Crises of this nature then become windows of opportunity for improvement and positive change usually incorporating aspects of social learning and evolution. Alternatively, the sensitivity may be too high and the resilience too low to withstand the hazard, and change may become permanent and irreversible with collapse of that SES (Gallopin 2006; Ehrlich and Ehrlich 1992; Adger 2001; Intergovernment Panel on Climate Change 2007; Reed et al. 2010).

Depending on the magnitude of the assault and length of the exposure, transformations may take place in subsections of an SES or may result in radical changes in the entire structure and behavior. Vulnerability can thus be defined as the sum total of the functional component attributes of the SES, which are sensitivity; capacity to respond, cope, or survive; and transformation adaptability and inherent social learning (Gallopin 2006; Vincent 2004). Social scientists try to express this in terms of a quantifiable social vulnerability index or SVI of a society, which inherently includes the economic vulnerability index (EVI) developed by the United Nations to identify least developed countries (United Nations Committee for Development Policy (UN CDP), http://www.un.org/en/development/desa/policy/cdp/ldc/ldc_criteria.shtml). This index takes into consideration the ability of the composite SES to anticipate, resist, cope with, and respond to hazards; that the society represents not just the individuals but also the economic, political, and social institutions that govern; and the integrity of the ecological state of the environment (Vincent 2004). In this context, social vulnerability is the sensitivity of the human environment, while biophysical vulnerability is the sensitivity of the natural environment to exposures. The degree of the cumulative effect will be determined by the magnitude of these two compounding coefficients, where, for instance, the SVI of a community will be particularly high when the human population that is exposed is historically disenfranchised, of low social status with poor health status, and the environment in which they reside is ecologically delicate or marginalized. These factors have been clearly articulated in the AR4 Working Group (WG) I, where widespread poverty, ill health, educational and institutional health deficiencies, slow acquisition of technology-driven economies, war, conflict, and government ineptitude all coalesce to form high vulnerability to unpredictable and destructive weather patterns. In such instances, even small weather phenomena can result in major catastrophe and human suffering.

When considering climatic aberrations, insidious changes irrespective of the SVI may allow shocks to be absorbed slowly and entertain a relative amount of adaptability, but eventually the coping capacity threshold will be reached and the state of the SES may undergo irreversible change. However, inclement weather events such as hurricanes, typhoons, tornadoes, flash flooding, and heat waves or cold snaps may give little time for response. Without the rapid response advance warning systems in place, which is an example of social learning adaptive transformation, impacts can be large in magnitude (Midgley et al. 2010; Davies et al. 2011; Brooks 2003; Moore 2004).

In defining the primary health care philosophy, the WHO in its Alma Ata Declaration of 1978 outlined health as not just the absence of disease or infirmity but a state of complete physical, mental, and social well-being. In the context of the huge burdens of disease that plague sub-Saharan Africa, in particular, HIV, TB, malaria, and malnutrition, wellness is relative, and large sectors of society have varying degrees of absence of disease or mental well-being. In addition, Southern Africa and to some extent much of sub-Saharan Africa is known to have a disproportionate number of economies in climate-sensitive geographical locations that are dependent on subsistence farming and devoid of water containment or food storage technologies, creating regional seasonal instabilities and forcing human movement. Almost one-third of Africa including much of Southern Africa is drought prone, and as populations increase the potential to exacerbate water stress is real (Midgley et al. 2008; Guillaumont and Simonet 2011a). This threat is significant even if there would be no long-term changes in the regional climate (Vörösmarty 2000).

Vulnerability in the African setting is a function of economic status, degree of marginalization, degree of physical freedom from multiple diseases and stress, the integrity of the physical environment, as well as the institutional structures, capacity, and the legislative policies that define the collective well-being of the society. Endowments of these institutional capacities are economically, politically, and technologically driven and are collective assets and social infrastructures that are the key components of the UNDP human development index (HDI). The HDI is a surrogate measure of the standard of living and quality of life in which health and longevity are critical components.

Within the human or social aspect of the SVI, there are numerous health perspectives to consider, such as the fragility of the individuals and their social networks; the ability of health care institutions to secure the well-being of its population before, during, and after shocks; and the health care and environmental policies that are in place to define the quality or the degree of wellness of the collective and the ecological integrity of the habitat in which the individuals live and derive benefit from natures free services (Shackleton and Shackleton 2011; Intergovernment Panel on Climate Change 2007).

Vulnerable populations are susceptible to inclement weather and inevitably suffer acute or chronic impacts especially if they reside in marginalized natural habitats.

Deepening poverty ensues with loss of livelihoods, which result in further loss of capacity to cope. Individual health status will deteriorate, and options for adaptations will be minimized. Where this occurs in rural communities, this would trigger population drift and urban migration, which are strongly associated with rates of HIV transmission (Voeten et al. 2010; Deane et al. 2010). War, drought, and other refugee-driven migration further compounds vulnerabilities in the urban setting, applying more pressure on the already stretched resources in ecologically fragile high-density informal settlements. Mental health is also challenged, as many of these migrants would have left behind social networks that may soften the impact of the adversities that they are likely to encounter in their new but harsh environments for which they have had little preparedness (Vincent 2004; Adger 2001; Coffee et al. 2005).

Key elements of social vulnerability are also contingent on social dependency and demographic structure of a community. Attributes of dependency are directly related to many of the indicators of the HDI, which refer to standards of living. The overall health of the population and the number of adults in gainful employment, free from reliance on welfare grants or bursaries, are indicators of a resilient society. Demographic structure is based on gender and age distribution and the complexity of the immediate social network. A community may have a normal or skewed distribution based on the forces that determine reproductive rate, good health, and longevity.

The current figures for national employment reveal that 35% of South Africa's employable population aged between 15 and 49 are without work, creating a huge sector of society highly dependable on national and social grants. The Government of South Africa is about to pass a new bill to introduce wage subsidies for unemployed youth aimed at creating opportunities for developing the skills of the 15- to 29-year old sector of society that has the worst unemployment rates. This is primarily aimed at retarding a growing security risk and social unrest that will ensue if the situation persists (National Treasury 2011; http://www.treasury.gov.za/documents/national%20budget/2011/Confronting%20youth%20unemployment%20-%20Policy%20options.pdf).

Incidentally this same age group has the highest HIV prevalence of about 16% (Dorrington et al. 2006). This produces reduced life expectancy and a skewed population composition and structure of mainly young people below the age of 15, with a weak or dying unproductive middle-aged group and a declining adult and aging population. This demography is not conducive or able to support a robust local and national economic growth projectile (Harrison 2010b; Intergovernment Panel on Climate Change 2007; Pachauri and Reisinger 2007). This is the reverse of developed countries where there is the cumulative aggregate of human capital with advancing age and expertise is retained in society, with huge returns for investment in lifetime skills and capacity development (Dorrington et al. 2006). This abnormal demographic composition caused by the HIV epidemic and unemployment promotes population vulnerability on many fronts and weakens household and institutional capacities, as national and household reserves and resources are diminished and what exists is diverted to the caring and maintenance of the sick and weak.

1.11.5 Origin of HIV and Its Propagation in Context of Changing Human Demographics and Environmental Vulnerabilities

At the advent of the agricultural era, critical masses of humans converged into stable communities in close proximity to domesticated animals, which permitted the cross-species zoonotic emergence of new human pathogens such as the flu from avian flu, small pox from monkey pox, and measles from rinderpest. Humans and animals share about 300 diseases, and 55% of human diseases are of animal origin. Most of man's worst infectious killer diseases such as TB, measles, cholera, influenza, malaria, and most recently HIV have originated from the animal kingdom that we have become closely associated with by virtue of changing human ecological interactions (Daily and Ehrlich 1995b; Gommes et al. 2004; Weiss 2001). These diseases have a short acute infective period and thus allowed the persistence of these infectious agents in the communities where humans exist in close proximity to one another (Black 1975). Such viruses that cause acute infections also appear to achieve greater heights of virulence when contracted from familiar members with similar genetic composition (Black 1992). HIV, which is directly related to the simian immunodeficiency virus (SIV), is another classic case of a viral opportunistic event that has emerged as a devastating human pathogen in a very rapid time frame of less than 50 years during a period spanning the colonial era in Africa. Severe disruptions of normal human ecological interactions and an unethical health care milieu created extreme susceptibility of indigenous Africans to a series of simian (monkey) to human cross-species events in the Congo River Basin, giving rise to the evolution of the HIV-1 virus subtype, the direct descendant of the SIVcpz, whose natural host is the chimpanzee (Moore 2004; Pepin 2011). Under normal conditions, humans are not particularly susceptible to SIV infections, but when conditions were right the virus gained access in severely stressed and immunologically suppressed humans and was subsequently able to evolve virulence and adapt as a new human pathogen capable of human-to-human transmission (Weiss 2001). Subsequently, a multitude of other demographic, trading, leisure, and mobility cofactors caused the rapid dissemination of the virus across the globe (Pepin 2011).

There are now at least 20 megacities with population sizes in excess of 10 million inhabitants worldwide and the number is set to rise. The twentieth century witnessed the rapid urbanization of the world's population. The global proportion of urban population increased from a mere 13% in 1900 to 29% in 1950 and, according to the 2005 revision of World Urbanization Prospects, reached 49% in 2005. Since the world is projected to continue to urbanize, 60% of the global population is expected to live in cities by 2030. These are unprecedented trends, and according to the latest United Nations population projections, 4.9 billion people are expected to be urban dwellers in 2030 (Midgley et al. 2010). In the past few decades, the human head count within the earth SES has reached 7 billion, which is the densest ratio of humanity to ecological systems that has ever been (Daily and Ehrlich 1995b). It comprises a large population of compromised individuals who live in mega overcrowded and polluted cities with poor nutrition and sanitation, creating the ideal circumstances for opportunistic infections and the evolution of virulence due to high transmission capacity (Moore 2004; Gommes et al. 2004; Weiss 2011; Marx et al. 2001).

In addition, large cities have the advantage of creating a sense of anonymity, which provides the freedom to act without the normal inhibitory mechanisms of a regulated society, promoting sexual freedom, prostitution, violence, and drug use, which are some of the main prerequisite conditions ideal for the transmission of HIV (Coffee et al. 2005). Movement of large populations of people can create disturbances in ecohabitats and balanced food chains, liberating certain populations of flora and fauna to expand uninhibited by the elimination of their natural predators. This has the potential for creating reservoirs for vectors of human disease and zoonotic potential in an increasingly immunocompromised population (Davies and Krebs 1993; Stiling 2001). The impact of human modernization and population dynamics giving rise to stress is almost certainly overlooked in the whole scheme of things. It is becoming clearer that stress in itself is a strong predisposing factor, increasing the susceptibility of humans and the animals they interact with to multiple infections. There are multiple causes of increased stress such as ambient temperature (too hot or too cold), inclement weather patterns, crowding, space confinement and poor ventilation, transportation issues, lack of economic empowerment, and the emotions associated with social defeat. These lead to a state of permanent metabolic alert characterized by insomnia and increased plasma cortisol and adrenalin, which are the fight and flight hormones. The physiologic and psychological stress and hassles of everyday life events in poor crowded living environments, lack of social support, and social family networks all diminish the robustness of the immune system and increase vulnerability and susceptibility of individuals to acute infections and reactivation of latent infections (Brogden 2002; Agarwal and Marshall 2001; Avitsur et al. 2009; Rozlog et al. 1999; Holloway et al. 2010; Walensky et al. 2008; Harrison 2010b).

1.11.6 Characteristics of the Key Preconditions Contributing to Current Vulnerabilities in South Africa, Status and Trends

1.11.6.1 HIV/AIDS

HIV is now the largest health burden confronting South Africans and threatens to wipe out the economic, social, and developmental gains achieved in the past century (Harrison 2010b). It is now consuming a large proportion of the health budget in South Africa, with attempts to roll out and implement the largest ARV program globally to support the estimated 5.5 million people living with HIV/AIDS. The HIV epidemic has reduced life expectancy from 52 years in 1997 to 43 years in 2007 (UNDP South Africa 2003). There should be an estimated 2.75 million people on ARV treatment by 2012 if recruitment onto treatment programs is effective (Dorrington et al. 2006; Walensky et al. 2008; Harrison 2010b).

1.11.6.2 Pathophysiology of HIV/AIDS

The adaptive immune system of humans comprises billions of white blood cells known as CD4 helper and CD8 killer lymphocytes, which represent a huge repertoire of protein recognition sites on their cell surfaces, whose specificity enables them to recognize and target with high specificity any possible foreign pathogen. Recognition by these cells of a pathogen that has gained access into a human system is followed by activation of a dramatic complex of cascading rapid response elements, CD4 and CD8 cell replication, and recruiting of other cellular components of the immune system in what is known as the cell-mediated inflammatory response.

The outcome of this inflammatory burst of activity is the elimination or containment of the invading pathogen. This highly specific pattern recognition function is stored and fine-tuned in the genetic program of each of the CD4 cells, which once exposed to a pathogen initiates the inflammatory response and will be subsequently retained as antigenic experience and designated as CD4 memory cells. As a result of this memory, subsequent exposure to the same pathogen will result in an exponentially faster and more specific response coordinated by the memory CD4 and CD8 cells, culminating in rapid clearance of the infection and generally not permitting full manifestation of the pathological consequences of that infective agent. These are the attributes of immunity that are exploited by vaccination technology. The CD4 cells are a major component of this adaptive immune system that orchestrate this highly specific immunological reaction of an individual aimed at eliminating foreign antigens or pathogens by focusing the CD8 cells, which then deliver their specific death signals to invading pathogens. The irony of HIV infection is that the target cell of choice for viral replication is the CD4 cell. This results in death and paralysis of billions of the ‘field marshal commanders’ of the immune system, resulting in a chaotic, disorganized, and depleted army of immune cells devoid of precision and coordination. This is the reason HIV is such a formidable pathogen and able to induce such profound immunological paralysis (Sompayrac 2012).

Following an exposure to the HIV (sex, needle stick, blood, or transplacental), a susceptible individual will manifest features of the primary infection, which are similar to symptoms of a flulike illness. Within a short period probably lasting a few weeks, the virus will devastate the immune system of the host by depleting majority of the memory CD4 cells that line the mucosal surfaces of the gut, lung, and genitourinary systems. This memory cell repertoire has taken the lifetime of the individual to develop and acquire and is almost virtually wiped out in a matter of a few weeks. This places the immune system in a state of near collapse and disarray and leaves the mucosal surfaces like the lining of the gut that should have a profound level of ‘CD4 memory’ immune surveillance and protection almost bare from an immunological perspective. This is described as the ‘leaky gut syndrome’ and is associated with loss of gut integrity, vulnerability to the translocation of large quantities of microbes from the gut into the blood stream, as well as degrees of malabsorption of vital nutrients. (Brenchley et al. 2004; Chang and Qin-xue 2009; Brenchley and Douek 2008; Downs 2010).

The immune system is able to partially and temporarily bring under control this acute devastation of immunological memory, and the infection transitions into a chronic phase, which may last from a few years to over a decade depending on the genetic makeup of the individual and environmental factors. In this time frame, the partially crippled immune system is unable to clear the HIV virus and is extremely vulnerable to microbe opportunistic infections and reactivation of latent pathogens like TB (CDC

Factsheets www.cdc.gov/hiv, Cancer in HIV IARCR, Cancers-Disease and Mortality in sub-Saharan Africa NCBI www.ncbi.nih.gov). Some of these opportunistic infections are notorious cancer-inducing viruses that the body is unable to eliminate swiftly and therefore predisposes to potential for cancer formation. The attrition rate of the CD4 cells is relentless nonetheless as the semiparalyzed immune system tries to recover under this persistent influx of pathogens from the gut and other mucosal surfaces and opportunistic infections. This complex sequence of events is responsible for keeping the body in a state of chronic immune activation (Ostrowski 2010). Eventually the disorganized immune system burns out and exhausts itself in this milieu of uncompensated activation and oxidative stress and then finally collapses as both the CD4 and CD8 cells decline dramatically in quantity and quality with the advent of several clinical conditions attributable to failed immunity. These conditions are typically characterized by TB reactivation, unusual opportunistic infections with fungal and parasite microbes, certain cancers such as lymphoma, Kaposi, and cervical cancer (Abayomi et al. 2011; Mantina et al. 2010; Wiggill et al. 2011). At this stage, when these events start to manifest, coupled with evidence of depleted CD4 cells in the blood which is determined by the 'CD4 count' blood test, the stage of the HIV infection is described as progressing into a state of acquired immune deficiency syndrome or AIDS. These events are also described as AIDS defining (Abayomi and Landis 2008; Abayomi et al. 2008).

Certain coexisting conditions predispose and increase the risk of acquiring HIV infection in the first instance and promote accelerated transition to the stage of AIDS after infection takes place. These are the presence of other simultaneous infections such as sexually transmitted disease; tropical diseases such as malaria, TB, tropical enteritis, and schistosomiasis; psychological stress; and protein–energy malnutrition, a state that is aggravated by the impact of the virus on the gut as described earlier (Bolton and Talman 2010; Anema et al. 2009).

South Africa is home to the world's largest population of young PLWH and has to date resulted in the deaths of at least 2.6 million South Africans, mostly children and young adults (Harrison 2010b; Avert 2010). Over 250 000 South Africans died of AIDS in 2008 (Harrison 2010a). HIV/AIDS accounted for about 75% of premature deaths in South Africa in 2010, up from 39% a decade ago (Bradshaw and Dorrington 2007). There are probably close to two million AIDS orphans rising in South Africa (UNEP UNAIDS 2008). Almost one-third of women aged 25–29 and over a quarter of men aged 30–34 are living with HIV (Harrison 2010b).

In response to the massive anti-HIV National Strategic Plan (NSP) under the South African National AIDS Council (SANAC), the HIV prevalence among people older than two has peaked and stabilized at about 11% and is likely to remain there for at least 5 years (Avert 2010; Scott and Harrison 2009). Women show a sustained rise from 5% in the late teens, reaching a peak of above 30% by 29 years of age and subsequently reverting to about 5% in 55–59 year olds. In men, the prevalence starts later at 5% in 20–24 year olds, reaching peak levels of 25% in 30–34 year olds. There are indications of significant declines among young people. Child mortality has probably also peaked and should decline further with increasing availability of treatment. The decline in prevalence in younger age groups is linked to better access to prevention of mother-to-child transmission and much higher self-reported condom use. The number of PLWH who now need to be recruited into the expanded antiretroviral program is estimated to be 2.25 million, increasing to 2.75 million by the end of 2012 (Walensky et al. 2008). People living in informal settlements have the highest rates of HIV infection (~20% in the urban informal compared to ~10% in rural-formal, informal, and urban-formal settings). Fragmentation of urban-transition, rural/urban, and regional migration patterns for economic or climatic reasons creates the conditions and vulnerabilities that fuel the spread of HIV (Harrison 2010b). Future trends suggest that the incidence of new cases will continue to fall, but the ARV program will maintain prevalence as PLWH will be set to live longer. Some coping mechanisms identified during environmental stresses like drought and floods are environmental desecration, migration, prostitution, and dispatching children away to relatives in distant locations. The continuous growth of large populations in crowded high-density and informal settlements with poor amenities has been identified to be hot spots for continued transmission that will facilitate new infections of HIV and TB. (McMichael 2008; Gommes et al. 2004; Holloway et al. 2010).

1.11.6.3 Tuberculosis (TB)

Between 6 and 10 million South Africans are believed to be infected with *Myobacterium tuberculosis*—a bacterium that causes TB. South Africa has one of the highest TB burdens in the world and is ranked third after Asian countries such as India and China (WHO 2010; Ndjeka 2011). TB is spread from infected persons to vulnerable persons in close proximity by airborne TB-laden droplets produced by aerosols that are generated by coughing. TB spread is facilitated by poor ventilation such as occurs in congested living conditions in shantytowns and houses or crowded public transport and by underlying lung injury. It is estimated that the small vaporized droplets of less than 2 microns produced by coughing can remain suspended for up to 4 h in a confined unventilated area. When breathed in by uninfected persons, these droplets are capable of penetrating to the smallest unit of the lungs where they multiply, creating the highest chance of causing active disease in human beings and particularly if factors in the community promote reduced immunity.

Exposure to TB in adults results in various clinical pictures. Some patients eradicate the bacteria completely with no immunodiagnostic evidence of exposure to the mycobacterium (Dheda et al. 2010). Most immune-competent persons will show immunodiagnostic evidence of exposure to the bacillus, with no clinical evidence of the disease (latent TB). In latent TB, patients do not have clinical symptoms of TB but the bacillus is present in the lungs in an immunologically controlled non-replicating state with a probability of progressing to active TB at any time in their lifetime when immune containment is weakened. Persons with a compromised immune system due to HIV, malnourishment, or stress are most likely to develop active TB at first exposure or reactivate latent disease (Dheda et al. 2010). Only a small fraction of normal and immune competent persons exposed to TB will develop active TB in their lifetime, estimated at about 12%, which is usually confined to the lungs or less frequently in a disseminated state affecting multiple organs and systems.

Widespread or disseminated TB results from hematogenous spread of mycobacteria from the lung to many organs (Grewal 2012; Schaaf et al. 2009). Common sites of spread include the bone marrow, lymph nodes, liver, spleen, brain, heart, and the skeletal, gastrointestinal, and genitourinary systems. Disseminated TB is associated with weakened immunity and is observed in children less than 3 years of age, elderly patients, and patients who are immunocompromised such as PLWH. In endemic areas, disseminated TB contributes significantly toward disease morbidity and mortality, particularly in countries with a high HIV infection prevalence (Reuter H et al. 2005). In children, the risk of developing active TB is higher while disseminated TB is seen more in children less than one year of age (Eamranond and Jaramillo 2001). Trends now reveal extremely worrying data indicating that drug-resistant TB (DR-TB) is on the increase in South Africa. DR-TB comprises collectively multidrug-resistant TB (MDR-TB) and XDR-TB. Six percent of re-treated TB cases and 1% of new cases are multidrug -resistant (MDR-TB), which translates to over 9000 cases in 2009, and a cumulative total of 45 000 MDR-TB cases have been diagnosed in South Africa between 2004 and 2010. (WHO 2010; Coetzee and Kroonhof 2006; Gandi et al. 2006; Becerra et al. 2010; Migliori et al. 2010).

1.11.6.4 Relationship between TB and HIV

As a result of the high background HIV prevalence in the society and poor overcrowded living conditions, TB is going through an unprecedented resurgence in South Africa (Harrison 2010).

The spread of the TB epidemic is closely related to the HIV epidemic, particularly in sub-Saharan Africa, which has the highest HIV prevalence rates in the world. In the setting of HIV, the risk of activating latent disease is increased by 10% per annum (Sudre et al. 1992). As indicated earlier, the incidence of TB in South Africa rose from 301 in 1990 to 971 per 100 000 people in 2009, representing a tripling of new cases in the past 20 years, which coincides with the growth of the HIV epidemic (Middelkoop et al. 2009). Of all the new TB patients, 58% were also infected with HIV (WHO 2010). The mortality rates in 2008 due to TB were reported as 153 per 100 000 people of which 66% were due to coinfection with HIV (Harrison 2010a). Unfortunately, there is no reliable data available for the incidence of TB in children in many African countries, including South Africa. Pediatric studies in South Africa have shown that TB is present in more than 40% of children infected with HIV. Children living with HIV have an unprecedented 24-fold increased risk of developing TB during their first year of life than children without HIV (Hesseling et al. 2009). The incidence of smear-positive TB has increased by between 200 and 300 new cases per 100 000 population annually in the presence of HIV. This does not take into account the numerous smear-negative patients who form a significant number of HIV-positive coinfected cases. It is in this setting that drug-resistant TB is set to become a major health issue (Ndjeka 2011).

1.11.6.5 Reciprocal Relationship between Food Security and HIV Complex Burden of Disease

The International Food Policy Research Institute (IFPRI) estimated that a minimum of 1800 kcal day^{-1} is required for most people to live a normal productive life (IFRI GHI 2011). The term undernutrition is defined by the IFPRI as deficiencies in energy, protein, essential vitamins, and minerals and may arise from inadequate intake or poor utilization due to illness and infection or combinations and will be referred to as protein energy malnutrition (PEM). PLWH have increased nutritional requirements in the form of an additional requirement of 400 kcal day^{-1} of energy and about 50–100% more of protein (East, Central, and Southern African Health Community (ECSA-HC), Food and Nutrition 2008; Mwadime et al. 2003). In the setting of coinfection with TB, these requirements are even higher (Macallan 1999). This fact is supported by the findings that demonstrate in low-resource areas where nutritive food assistance supplementation given to PLWH resulted in both weight gain and retardation of disease progression particularly for those not on ARV or at advanced stages of the disease (Rawat et al. 2010).

In the three decades preceding the turn of the century, 65% of persons living in sub-Saharan Africa were judged to be living in absolute poverty and undernourished (Chambers 1995, 1997). This ironically coincides with the emergence of the rapid escalation of the HIV epidemic in the region. The Food and Agriculture Organization (FAO) has released dramatic statistics estimating the magnitude of PEM in the subregion of southern Africa. Estimates of the order of 95 million people are believed to be living under the threshold calorie intake for normal healthy nutritional status, and the trend in the past decade is deteriorating (Confalonieri et al. 2007; De Wit 2010). Data on the global hunger index (GHI) released in 2011 by IFPRI shows that sub-Saharan Africa has one of the worst hunger index scores worldwide, with many of the southern Africa regional countries in the severe to alarming scales of the GHI. In South Africa, malnutrition rates have deteriorated in the past decade. Recent findings indicate that one in five children are stunted and one-third of women and children were anemic, while two-thirds of children have vitamin A deficiency and almost a half were iodine deficient (Gasa 2009). This publication states that there are an estimated 14 million people who are food insecure and 1.5 million children who suffer from PEM in South Africa and goes on to elucidate the main reasons for this concerning data. The main factors responsible for this are massive unemployment rates of between 35 and 40% nationwide, and South Africa ranks third on the global list of most unequal economies, with the largest gaps between the rich and the poor. The government's attempts to eradicate extreme poverty has seen the social assistant grants rising from Rand 10 billion (∼US$1.3bn) in 1994 to Rand 40 billion (∼US$6.0bn) in 2004 and still rising with the number of beneficiaries quadrupling. In some provinces of South Africa unemployment is as high as 93%, and nationally 55% of the working population had monthly incomes of between 1 and 1000 South African Rand, the equivalent of 10 cents and $140 USD. Despite interventions there are hot spots that are poverty nodes in rural and urban sectors caused by increasing unemployment, rising food prices, HIV/AIDS, adverse environmental and climatic conditions leading to declining crop and livestock production attributable to increasing heat, decreasing moisture, and unpredictable growing seasons. In some cases, excessive precipitation can also result in both crop failure and dramatic livestock losses. A recent survey in South Africa by the

Health Science Research Council (HSRC) analyzing the nutrient and balanced dietary intake index (dietary diverse score (DDS)) as an indicator of adequate nutrient intake found that 40% of all South Africans had inadequate intake of nutrients, and this ranged from 15% in some provinces to as high as 62% in the worst affected areas. When dissected per type of location, rural and urban informal settlement had the worst profiles with greater than 50% evidence of PEM based on intake as compared to 26% in urban formal locations (Human Science Research Council 2011).

PEM lowers immunity and predisposes people to infection. Evidence now clearly demonstrates that any person with an infection has a significantly higher protein and calorie requirement. Populations with a high prevalence of PEM (as in Southern Africa) are more prone to be infected by the multiplicity of tropical infectious diseases in the environment (Chatraw et al. 2008; de Waal and Whiteside 2003). Furthermore, infection in this setting of PEM compounds the situation and causes further deterioration of the existing nutritional status, ushering in a vicious cycle of worsening nutritional deficit, fading immune status, and super or multiple coexisting infections or even death (Macallan 2009). The combined effect of PEM and infection is profoundly synergistic and lead to metabolic effects that cannot be rectified by antimicrobial treatment alone and must incorporate nutrient replacement strategies for maximal effect (Chatraw et al. 2008; Fawzi et al. 2007a,b). Children are particularly prone to the effects of PEM because it causes developmental retardation or involution of the thymus gland. The thymus gland is central and critical to the orchestration of an effective immune system, as the CD4 and CD8 cells are nurtured and developed in this organ. These are the immune cells that would be responsible for resisting the invasion of the body by an HIV virus. Furthermore, infection in childhood requires higher supplementation with protein and calories when compared to adults (Keusch and Medlin 2003).

These trends demonstrate the profound relationship between the environment, food security, and the infection profile of a community and region. The evidence is that sub-Saharan Africa, which has the world's highest burden of infectious disease, is the only region showing a growing proportion of undernourished populations predisposed to infection and death. This can be attributed to many sociopolitical factors, but certainly there are records of historical abnormal weather patterns as far back as the post-Second World War era that have influenced food security in the whole region (Ambrus and Ambrus 2004a,b). Specifically and in the context of HIV and PLWH, PEM is responsible for lower CD4 counts and higher viral load indicative of poorer control of viral replication. PLWH who are food insecure are less likely to start ARV or maintain the necessary adherence of >90% to achieve the required viral suppression associated with longevity and improved prognosis. PEM is associated with a compromised ability to suppress the virus to undetectable levels, which is the desired gold standard of effective treatment in patients on ARV therapy. Therefore, the preexistence and concomitant presence of PEM renders treatment less effective (Weiser et al. 2009; Wang 2011).

Risk of horizontal and vertical transmission is increased in PEM because of higher viral burden, lower immune and mucosal protection, and the tendency to engaging in risky behavior such as transactional sex out of the need to alleviate food deprivation. Undernutrition facilitates the acquisition and spread of HIV infection in the first instance and at the same time aggravates the resulting chronic HIV burden of disease. The resulting physical incapacitation and loss of well-being leads to further deterioration of food security (Anema et al. 2009). This complex is referred to as the new variant famine (NVF) in Southern Africa. In normal circumstances, populations employ a variety of coping and adaptive mechanisms to get through and survive shocks such as crop failure by redirecting savings or disposing of assets for a brief period till the shock is overcome and normalcy is reestablished. In populations with medium to high prevalence of HIV, recovery is impaired by those infected and affected by the disease, and as a result households and communities are likely to descend into poverty rather than ride the tide (de Waal and Whiteside 2003; Naysmith et al. 2009).

In South Africa, where food is not technically in short production, adequate nutrition is not accessible to a large sector of the society that is located either in large informal settlements or in rural locations most vulnerable to PEM because people depend on rain-fed agricultural traditional systems for subsistence. Macroeconomic reasons among other factors associated with a heterogeneously diverse economic landscape are responsible for this dichotomy (McMichael 2008; de Waal and Whiteside 2003; SADB 2008; McMichael and Butler 2009).

1.11.7 HIV-Induced Human and Environmental Vulnerabilities and Effects of Climate

A significant proportion of South Africans have serious and complex health challenges as outlined earlier, emanating from the recent political and social circumstances that characterized the colonial and apartheid eras in the histories of the subregion. These health issues were certainly compounded by forced human displacement and poor subhuman living conditions, the remnants of which are clearly visible in numerous and dense informal settlements (Holloway et al. 2010; Kilian et al. 2005). This scenario creates and constitutes a people with a unique disease complex as outlined earlier in this chapter. Underpinning these conditions are the common denominators of poverty and lack of social amenities (Midgley et al. 2008).

In the Third Assessment report of the IPCC (IPCC TAR WGII 2001), human health vulnerabilities are categorized in three tier levels:

Individual

- Disease status of population (environmental stressors increases disease status proportionately)
- Poverty (lowers resistance to health challenges)
- Demographics (percentage of susceptible: young and elderly)

Community

- Water quality and quantity
- Food supply, storage, and distribution
- Access to information and ability to galvanize response
- Local disease vector distribution and control programs

Geographical

- Extreme weather patterns peculiar to a locality
- Population living in low-lying coastal areas
- Population on the boundary of a known vector-borne disease
- Rural population may have poor access to health infrastructure
- Urban population susceptible to effects of crowding
- Extent of environmental degradation and air pollution

South Africa is a relatively dry and temperate country with an annual rainfall of about 500 mm, with most of its water obtained from surface water entrapment. Weather patterns have been observed to change in the past 50 years, with significant trends toward consistent but gradual warming and changes in temporal and spatial precipitation characterized by increase in intensity and duration per event interspersed by longer dry spells (Christy et al. 2009; Pielke et al. 2006). Temperature trends may be due to land-use change and siting issues, in addition to any changes from added CO_2 and other greenhouse gases (Christy et al. 2009). There are unresolved issues with the assessment of multidecadal global land surface temperature trends, and there are no reliable regional predictive skills (Pielke et al. 2011, 2006; Pielke 2012 blog). As most of the national water is already fully committed, any changes in climatic conditions would likely have major impacts on economic development, health, and livelihoods by directly influencing water quality for human use, food security, flooding events, loss of biodiversity, and warming with increasing episodes of heat waves and inversion days (brown haze). With specific reference to health, these changes would impact air and water quality, with increased pulmonary complications and waterborne diseases, as well as have a direct effect on human physiology during heat waves (Haines et al. 2006). Fewer but heavier flooding and increased fire events would have consequential acute direct physical damage and resultant stress (Midgley et al. 2005). In PLWH, these conditions would likely have adverse health effects because respiratory reserve is already compromised by TB and gut integrity is suboptimal with increased susceptibility to nutrient deficiency, opportunistic infections, and gastroenteritis.

1.11.7.1 Scenarios in South Africa and Possible Thresholds for PLWH

1.11.7.1.1 Heat Stress

These effects exhibit spatial and temporal variability across regions. The extremes of age groups, those with existing chronic ill health like HIV/AIDS especially, and the low socioeconomic strata are especially vulnerable (Midgley et al. 2008; South Africa's Second National Communication on Climate Change 2011; Bambrick et al. 2008). The human physiology is designed to function optimally at environmental temperatures ranging between 17 and 31 °C (McMichael 2008). When ambient temperatures exceed 34 °C, the risk of hyperthermia is high. In the absence of corrective measures, dehydration and multiorgan instability will ensue, resulting in exhaustion, ill health, and death from cardiovascular collapse within a short time frame. Data from South Africa over four decades indicate that the number of hotter days and nights are increasing, especially in the interior, while cooler days and nights are decreasing, suggesting that warming trend may possibly result in increased casualties from heat stress (South Africa's Second National Communication on Climate Change 2011). Data from Malawi suggests that even in the early stages of HIV infection, kidney function can be compromised in as many as 60% of patients from a direct effect of the virus on the kidney. The kidney is a key organ in regulating water and intravascular volume, which maintains normal blood pressure critical for vital functioning of all organs (Struik et al. 2011). Furthermore, certain ARV drugs used to treat HIV have direct kidney toxicity profiles and can in themselves lead to progressive renal failure (Daugas et al. 2005). PLWH are more prone to dehydration, especially if they are in the late stage of the disease and have other complications associated with fevers. This is particularly true of frequent gastrointestinal disturbances such as diarrhea and mouth ulcers, which predispose PLWH to dehydration and malabsorption of critical minerals, proteins, and fluid (Garcia-Prats et al. 2009).

1.11.7.1.2 Storms and Flooding

The health impacts of catastrophic and extreme weather events are well known. Disaster occurs when these climate hazards converge with a vulnerable population, resulting in severe structural damage and social disruption that can result in profound psychological impact and behavioral changes when trying to cope. Some of the main factors driving or shaping vulnerabilities are population growth and concentration in high-risk areas, compounding poverty and environmental degradation typically seen in the informal settlement areas where HIV prevalence is highest and also typically the only location that can potentially accommodate climate and economic refugees. There is great risk of environmental pollution, social dislocation, and infectious epidemics during such catastrophic events (Midgley et al. 2008; Holloway et al. 2010; South Africa's Second National Communication on Climate Change 2011).

1.11.7.1.3 Waterborne Diseases

Waterborne infectious diseases are any illnesses caused by the consumption or usage of contaminated water. These conditions have a close association with aberrant weather patterns and disaster situations (McMichael 2008). Typical PLWH are very prone to these waterborne infectious disease pathogens including bacteria, viruses, and protozoans. Waterborne infectious diseases pose an acute problem in areas where populations are expanding and water supply and sanitation infrastructure are either rudimentary or nonexistent as are typically seen in informal settlements (Thambiran 2008). The most common waterborne infectious diseases in South Africa include cholera, dysentery, typhoid, and other rotavirus infections. El Niño–Southern Oscillation (ENSO) is regarded as the strongest naturally occurring source of climate variability that directly or indirectly affects factors that influence outbreaks of these waterborne diseases and can shift the timing and duration of such on an annual basis. The links between weather and diseases are well established, as many diseases are seasonal or occur during or after unseasonal extreme events such as floods or drought (Rozlog et al. 1999). Studies provided some quantitative evidence for the link between climate and cholera outbreaks. A study was based on one of the longest available health data sets (from Bangladesh for 1893–2001), where a strong and consistent ENSO signature for the period 1980–2001 explained 70% of the excess variance of cholera at the time (Patz 2002).

Exploitable water supplies in South Africa are confined to rivers, artificial impoundments, and groundwater. The total capacity of impoundments amounts to more than 50% of South Africa's total average annual river runoff (Oberholster et al. 2005; Wilson et al. 2005). Changes in precipitation and evaporation would dramatically affect the quantity and quality of these sources of water and predispose to waterborne diseases. Africa had 94% (179 323 cases) of global cholera cases in 2008 (WHO 2009), 12 752 of which were in South Africa (Ottawa Charter for Health Promotion 1986; OCHA 2009).

South Africa is at risk of cholera and other waterborne diarrheal outbreaks because of its historical precedents of such outbreaks, proximity to neighboring countries where many of the microbes causing diarrhea are known to be endemic, the movement of people between these areas and South Africa, the number of poor and vulnerable people dependent on natural water, and environmental conditions conducive to the survival and growth of these pathogens, including hot rainy summers, droughts, estuaries, and port cities. Communities in areas with no or limited access to safe water supplies and sanitation, poor or limited health infrastructure, and unfavorable socioeconomic and environmental conditions will always be at risk of cholera and other waterborne diarrheal outbreaks. Overcrowding plays an important role in the rate of spread of these gastrointestinal pathogens (Lucas et al. 2005; Soto 2009; Collins 1996). Cholera in particular produces a dramatic depletion of intravascular volume in a short time by copious vomiting and diarrhea. PLWH are especially prone to waterborne diseases of this nature and probably have less physiological reserve than non-HIV infected persons as outlined earlier, causing faster collapse of cardiovascular systems and renal function, resulting in higher morbidity and mortality. In an outbreak of cholera in Kwazulu Natal in the year 2000, attending doctors were sometimes unable to distinguish the profound diarrheal disorders found in AIDS from that of typical cholera. In the setting of existing HIV infection, cholera is likely to cause higher morbidity and mortality especially when socioeconomic circumstances are poor and the population has a high HIV complex disease burden (http://www.bvsde.paho.org/texcom/colera/choleraNatal.pdf).

In a report from Haiti following the recent earthquake causing thousands of displaced people, a cholera outbreak that ensued was found to be most devastating among HIV-positive persons, causing rapid collapse and death in about 2–3 h compared to non-HIV infected people. (http://www.irinnews.org/Report/91152/HAITI-HIV-positive-people-especially-vulnerable-to-cholera).

1.11.7.2 Air Quality

The planetary boundary layer (PBL) is the lowest part of the atmosphere, ranging anywhere between 100 and 2000 m above the surface of the ground. Its behavior and properties are directly influenced by the topography of the earth's surface. The flow of wind in this layer is typically turbulent and responds to surface forcing such as temperature, resistance or drag, moisture, and ecological complexity. These forces are important in affecting weather patterns and the rate of exchange of particulate matter (PM) between the PBL and the free atmosphere above it (Seidel et al. 2010). Precipitation in particular acts as the main sink for suspended PM, while wind causes dispersion (Jacob and Winner 2009). Stagnant air episodes occur primarily in winter, when inversion conditions occur, trapping pollutants and increasing their concentrations within the PBL. The air pollution disappears only when the inversion is broken up by wind, rain, or the warming effect of the sun. Human-generated emissions affect air quality and subsequently human health. Exposure to air pollutants, such as PM, sulfur dioxide, ozone, and nitrogen dioxide, is associated with a depressed immune system and cardiorespiratory morbidity and mortality (Pope et al. 2002; Brook et al. 2004).

A significant air-related health effect of pollution is in relation to ozone, PM, and brown haze content of the PBL, especially in urban areas, all resulting from fossil fuels. Ozone, even at relatively low levels, when inhaled has been associated with pulmonary damage and asthma attacks (Mittal et al. 2007). The size of the PM in air suspension determines its capacity aerodynamically to be inhaled and to penetrate the lungs, either causing local damage to the lungs or being able to penetrate into the circulation. These sizes range from the largest at PM10 (10 μm) to the smallest ultrafine particles (UFPs) (0.1 μm in diameter), which result mainly from combustion processes. UFPs demonstrate very high capacity to penetrate and deposit deep in the human lungs and alveoli, potentially leading to enhanced biological toxicity. UFPs may even be able to pass directly through the lung lining into the blood, which could allow them to be disseminated systemically though the blood with profound systemic effects (Brook et al. 2004). All these factors have a detrimental effect on PLWH who have compromised lung function from frequent pneumonic episodes and pulmonary TB with residual lung fibrosis. The permeation of fine air pollutant PM through the lung lining into the blood stream causes additional oxidative stress toxicity to the blood vessel lining in the setting of high levels of existing oxidative stress generated by the chronic inflammation of HIV infection predisposing to vascular complications (Abayomi et al. 2008; Brook et al. 2004).

Indoor air pollution is also a major concern, as almost one-third of homes in South Africa rely on indoor burning of fossil fuel particularly in the homes of indigenous Africans in high-density locations and informal settlements. Limited ventilation in these homes coupled with overcrowding makes this scenario a health hazard. Indoor pollution is associated with increased risk of chronic obstructive airway disease (COAD), asthma, bronchopneumonia, and TB, especially in young children or adults with underlying lung disease, cardiovascular disease, or HIV/AIDS (Norman et al. 2007a,b). Norman et al. propose that the underlying HIV infection and PEM work synergistically with indoor pollution to increase the risk of these complications. Climatic conditions provide increased exposure risk to these conditions when climate-induced migration force crowding in informal settlements or there are episodes of cold snaps or prolonged rain-induced cold and damp (Holloway et al. 2010).

1.11.8 Adaptation

Coping mechanisms identified during environmental stresses such as drought and floods are migration of one or all members of a family, dispatching children away to relatives in distant locations, consumption of assets, exploitation of natural resources, remittance of funds from relatives, and prostitution. Dislocation of family units and transactional sex increase the risk of HIV transmission (Pettengell 2010; MIDSA 2009). Where migration results in loss of man power and brain drain from the region as a whole, it also poses even more challenges to the dearth of skills appropriate to accommodate regional economic growth, a concern that was initially addressed by the Joint Initiative Project for Skills Acquisition and more recently the New Growth Path Initiative, which has a main mandate of addressing massive joblessness, poverty, and inequality (MIDSA 2009; New Growth Path Initiative 2009). Unplanned rural to urban population shifts place further strain on already overcrowded high-density locations close to and within major towns and cities. These locations are characterized by poor amenities, antisocial habits of crime and drug abuse in the setting of poverty, and unemployment and hopelessness, creating the perfect milieu and negative feedback loops that feed into the HIV epidemic (Bolton and Talman 2010). Lack of organized housing infrastructure in these localities will result in increasing exposure to indoor and outdoor air pollution, flooding and dampness, water and environmental pollution, and risk of fire, violence, and abuse (Holloway et al. 2010; Kilian et al. 2005).

In South Africa, the urbanization rate now is estimated to be 62% to small towns and cities, with rapidly growing informal settlements usually on degraded or unsuitable land (SADB 2008; South Africa's Second National Communication on Climate Change 2011). Crowded urban settlements are associated with an increase in social diseases, stress, and negative impact on vulnerability indices as previously described. (Pachauri and Reisinger 2007; Kilian et al. 2005).

Butler and Harley (2010) classify the threat of climatic and ecological effects to human well-being in three dimension in the form of the primary direct effect such as the acute impact of heat waves or flooding; secondary indirect effects produced by changing epidemiology of infectious disease; and tertiary effects, which are more serious and encompass famine, mass migration conflict, epidemics, and war and urge the medical profession to view this complex phenomenon holistically and in all its ramifications.

The relationships between HIV, the environment, and climate are interrelated and very complex with multiple pathways and negative feedback loops and have features that cross over from Butlers description of secondary and tertiary impacts of climate change. Impoverishment is the end point of all these factors and negatively affects the ability of individuals and collectively as communities to rise to challenges and cope with new stresses, hazards, and shocks. Methods by which affected individuals respond to stress may be beneficial as in positive adaptations or retrogression depending on social structures, access to information, or availability of resources. Ultimately, if wrong choices are made increased vulnerability of communities to HIV and environments to degradation can and will ensue (Butler and Harley 2010; Stillwaggon 2006). HIV is often perceived in its simplistic terms of engaging in risky behavior without understanding the context in which these choices are made. Poverty creates vulnerabilities that determine certain human behavior, sometimes beyond the thresholds of reasonable decision making. This increases vulnerability to HIV infection, which in turn creates further poverty in downward spiraling cycles of human and environmental degradation. Africa has been impoverished by decades of injustice, harsh weather patterns, PEM, and a complex myriad of infective agents in the setting of limited access to medical resources. If adaptations are now going to be effective, then the processes that produced the disenfranchisement should be addressed and the population reempowered to make adaptive and grass roots decisions in the context of self-determination and indigenous knowledge systems (Pettengell 2010; Stillwaggon 2006).

Under the auspices of the WHO Regional Committee for Africa, the framework for public health adaptation to climate was adopted by all regional health ministers by committing to identifying and documenting baseline parameters of risk in concert with capacity resources both human and infrastructure within the region and aligning this to the index of vulnerability with a view to ramping up health infrastructure as an adaptive measure. These would embrace overlapping goals within the MDGs and lay focus on water and sanitation.

In South Africa specifically, attention is directed at HIV, TB, and PEM through several strategic initiatives within the Department of Health (DOH). There is a critical shortage of health care personnel across the continent characterized by a brain drain not only from the public to the private sector but also from loss of human capital to developed economies. To achieve the goals outlined by the policies clearly laid out by regional ministers of health and particularly the DOH in South Africa, greater attention must be paid to producing more health care personnel and improving conditions of service that prevent this drainage phenomenon in this key sector. This can only be achieved by greater health care allied sector financing as a percentage of the GDP expenditure. A concerted and determined effort backed by strong political will and engagement is required to galvanize a robust and strategic approach to a multitude of deficiencies within our national and subregional institutions. Furthermore, the approach needs to be driven by an intersectorial framework with a common agenda aimed at strengthening multiple public infrastructures and resilience rather than the isolated attempts of each segment of public service attempting to rise to the challenge, which will inevitably be a weak and compartmentalized in approach and impact. The multiple foes affecting the community all have in common a unified denominator of success that resides in raising standards of living and both human and institutional resilience (New Growth Path Initiative 2009; AsgiSA 2012).

1.11.8.1 HIV/AIDS

Despite a national policy for initiating ARV treatment at a CD4 count of 200/μl (the CD4 blood count measures the damage to the immune system and is used to trigger various treatment strategies), most PLWH are starting ARV therapy at counts less than 100/μl (Avert 2010). Furthermore, the ARV program coverage rate is currently only 30% effective. This reflects the inadequate identification and recruitment of PLWH who qualify for treatment, which may be related to issues of stigma and lack of information. The consequence of this late commencement of ARV is poor regeneration of the immune systems, leading later to major morbidity and mortality and eroding the initial benefits of ARVs (Abayomi et al. 2011). There are clear immediate and long-term clinical benefits to starting ARVs at a minimum CD4 count of 200/μl (Badri et al. 2006; Kaufmann et al. 2005), and there needs to be greater efforts to achieve the goals set by the national policies. The initiation of ARVs at a threshold of 350/μl in pregnant women has been shown to virtually eliminate vertical transmission and is likely to be highly cost-effective (Mofenson 2009; Mofenson et al. 2009). Similarly, earlier initiation of ARV in PLWH who are coinfected with TB is likely to lead to significant savings (Lawn et al. 2007; Lawn and Wood 2007a,b).

For these reasons, South Africa has changed its policy as of 1 December 2009 to expand the ARV program to include pregnant women with CD4 counts ≤350/μl (Harrison 2010b). However, for the rest of the population, all efforts should be made to commence ARVs as close to a CD4 count of 200/μl as possible, although it appears that national policy is swinging toward adopting 350/μl as a standard threshold for commencement of ARVs for all. Initiatives focused on the manufacturing of ARVs in South Africa and finding more cost-effective indigenous platforms to carry out HIV testing and laboratory monitoring, as these currently account for 80% of costs of ARV programs, are in progress and highly laudable (Cleary et al. 2010; Cleary and McIntyre 2010; Kevany et al. 2009). The DOH of South Africa backed by powerful Government will has also initiated an ambitious program to identify all persons living with HIV through massive nationwide counseling and testing drives, which should provide a much-needed basis for aggressive recruitment into ARV treatment programs (DOH 2011).

Stigma barriers need to be overcome, and greater emphasis needs to be placed on encouraging the population to identify their HIV status and present early for sustained medical attention characterized by early commencement of ARVs with good adherence, which will translate to beneficial immune recovery (Sabin and Phillips 2009).

1.11.8.2 Tuberculosis

Ideally an effective vaccine against TB would have dramatic preventative impact especially in the context of drug-resistant strains. However, no progress has been forthcoming on this front, and the existing BCG vaccine only has temporary effect on children in their formative years, protecting them from severe complications of TB should they acquire the infection (Abu-Raddad et al. 2009). TB can usually be cured by a 6-month regimen of treatment. However, multidrug-resistant TB requires more sophisticated and costly treatment (Lawn and Churchyard 2009). The emergence of this phenomenon represents a major public health threat in South Africa, not just to the community but also to health care providers (DOH 10 point plan progress report 2011). Managing TB, especially multidrug-resistant TB, requires a heightened response with a focus on earlier detection at community level, improved patient compliance, and adequate drug sensitivity profiling (Basu et al. 2009).

Recent developments utilizing the new molecular-based test for DR-TB also known as the GeneXpert is about to be rolled out across South Africa as it provides fast and rapid identification of drug-resistant strains of TB on sputum smear-positive cases in a matter of hours as opposed to 6 weeks by conventional drug sensitivity mycobacteria growth indicator tube (MGIT) testing (DOH DR-TB report 2011). Health care environments must have suitable safety features to protect both caregivers and other patients. Particular attention must be placed on minimizing interruption and defaulter rates with good monitoring of smear-positive conversion rates after 2 months of TB treatment as a first benchmark of good response (DOH 2011). The ability to distinguish latent quiescent infection from active TB, particularly in HIV patients, is critical. Many HIV patients who have concurrent TB will be sputum negative and therefore not be amenable to standard laboratory diagnostic tests, which rely on the presence of the TB bacillus in the sputum. Ground-breaking work in identifying blood tests that can rapidly make these distinctions is being carried out by scientists from the continent (Adekambi et al. 2012; Chegou et al. 2009; Walzl et al. 2011; Djoba Siawaya et al. 2009). TB must be identified early in both its latent and masked active forms irrespective of sputum positivity, such that appropriate treatment can be commenced to protect the community and health care human personnel by pharmacologically quarantining the infective agent, thus minimizing its capacity to be transmitted to both normal and particularly vulnerable members of the community.

1.11.8.3 Nutrition and Health Infrastructure

At the heart of all health adaptation strategies must lie sound nutritional policies. If a population's nutritional status is robust with attention to the correct balance between proteins, energy, lipid, and micronutrients, then individuals will have greater resilience. More attention needs to be paid to children's nutritional status and particularly girls who will become key determinants of their future family nutritional profiles (Chapman et al. 2011). The interaction between malnutrition and infection requires focused attention to effectively combat prevailing and potentially emerging infectious epidemics (de Waal and Whiteside 2003; Macallan 2009; Keusch 2003). Health care capacity is a key component of developmental growth and stability and central to all adaptation strategies. Poor infrastructure and inadequate human resource is a barrier to any governmental plans for rural and urban welfare and alleviation of poverty goals. Issues of spatial location of health facilities, retention of skilled human resources, incentives to attract these resources to rural communities are all key issues that need urgent attention.

1.11.8.4 Drastic Circumstances Need Drastic Solutions

The turn of the twentieth century saw the advent of the antimicrobial, when man accidentally stumbled upon the biological agent known as penicillin. This happened in parallel with the industrial age ushering in the dawn of antimicrobial therapy with the advent of the hypodermic needle, establishing an era characterized by a surge in medical knowledge, use of antimicrobials, vaccinations, and organized health care delivery (Daily and Ehrlich 1995b; Marx et al. 2001). This created the environment for a dramatic increase in human population from about two billion in 1927 to a staggering seven billion in just under 100 years, and is estimated to grow to eight billion in the next 20 years (UN population figures).

The consequence of this dramatic population boom is inevitable food insecurity (McMichael 2001). This era has been characterized by massive rural to urban shifts and aging populations, which has worsened access to food and space for recreation. It is also attended by a rapidly growing human ecological footprint, increasing emission of fossil fuel into the atmosphere, environmental degradation, and the formation of giant agglomerations or megacities (Daily and Ehrlich 1995c). With exponentially increasing technical and medical expertise, humanity has stepped into the genetic age. We are currently living in the genetic manipulation era, which is characterized by man's capacity to successfully and rapidly sequence the entire genetic programs of all life forms. With this in mind there is the great temptation to explore the possibility to completely take responsibility for modifying the environment that we live in by creating biological organisms with modified genetic information that will meet the needs of a growing and high demand populace in a deteriorating ecological environment (McMichael and Woodruff 2002; Abayomi and Jacobs 2009). We may even be forced to modify the human genome to cope in a rapidly degrading and resource-constrained world that is losing the benefits supplied to human societies by natural resources. In the absence of a vaccine solution for the HIV scourge and the huge logistics of keeping millions of people alive in a region that is struggling to feed itself in hostile climatic conditions, the ARV roll out programs are expensive, technically cumbersome, and probably in the long run unsustainable. A drastic solution is needed now more than ever.

1.11.9 Conclusion

Despite Africa's incredible endowments in human diversity and natural resources, the impact of the HIV/AIDS epidemic has caused most economies of the countries south of the Sahara to experience reversal trends synonymous with economic backpedaling. This is why the simplest of goals known as the MDGs seem almost too high a dream to achieve. When one imagines that in fact the MDGs are not development goals by any stretch of the imagination but in fact simply targets to attempt to pull a whole continent out of share and abject poverty, it would only be at the point of attaining the MDGs and some semblance global social justice that Africa as a geopolitical space can speak of embarking on a new road of development. Coupled with shrinking global economies, the effect of HIV on human health, our most important resource, has been nothing short of catastrophic especially as the continent just seemed to be emerging out of the successive throes of slavery and colonialism in the mid-twentieth century. It appears that the continent has not been allowed to develop a stable and critical threshold of human capital to grow and drive its potential for sociotechnical development and geopolitical stability. Like a sleeping giant trying to emerge out of the rubble, the continent is now faced with further deterrents to growth in the form of threats from climatic conditions. However, perspective should be maintained and changes in climate statistics represent only a subset of climate, and even if there would be a change in these statistics, the other threats reviewed in this chapter show them to be dominant. Climate in all its ramifications is not a new phenomenon but is a series of events that has insidiously and perniciously crept up over the decades slowly corroding economic stability by further undermining the health and productivity of the continent. Most feared of all are its twin potential to undermine the livelihood and well-being of the people most dependent on stable or predictable climate and the latent ability to induce conflicts over water and arable land. The linkages between climate and HIV are numerous and intertwined at so many levels, and it is impossible to say where one starts, for until today one cannot say for sure which came first and when it started. Their negative impacts seem to feed off one another synergistically to the detriment of all people on the continent. What is sure is that we must overcome both menaces with the full might of the collective resources of humanity if we are to emerge victorious, and the world cannot sit back and watch Africa solve the problem on its own, because in the spirit of Ubuntu we are all one and live for one another. Extreme poverty, disease, and suffering in one part of the world creates instability and unrest in another. South Africa and its surrounding countries are contending with a major public health threat created by HIV and the attending downstream medical and livelihood complications that ensue in an environment with high prevalence rates. These effects culminate in the increasing vulnerability of the affected population and the ecological environments that are subject to exploitation when other options for livelihood are limited.

Multipronged strategic and measured approaches are required to alleviate now the double scourge of HIV and climate on the subcontinent of Africa, but central to the tasks are the alleviation of disenfranchisement and the restoration of self-governance and determination. The cost of mitigation and adaptation must be borne by the collective humanity as a separate entity to the huge needs to address underdevelopment through the MDGs. HIV and TB must be tackled face on as a global emergency and not as a business opportunity for the pharmaceutical industry and medical fraternities. Nor should it be turned into an exercise of rhetorical aid agencies branding imposing solutions on indigenous people. A radical simple and effective solution to pathogenicity of HIV needs to be found in the interest of humanity and should be devoid of commercial capitalization.

The solution to the eradication of the HIV/AIDS problem has been in our grasp for decades, yet there are millions at risk and millions dying on a yearly basis, dying at an age when they could be most constructive to the economic and political development of the nations of Africa and the world as a whole. For every person's premature demise and unfulfilled life is a loss to the world as a whole. Nelson Mandela, whose last surviving son died of AIDS, the icon of freedom and social justice, spoke these words in 2004: "By all accounts, we are dealing with the greatest health crisis in human history. By all measures, we have failed in our quest to contain and treat this scourge." Eight years down the line, we are no further toward achieving a solution, and with climatic change hot on our heels we are at critical times in our history.

Given what we know now about the evolution of pathogenic virulence, the nexus between human exploitation, environmental integrity, climate, social interactions, conflict, malnutrition, and disease, empirical evidence strongly supports a premise. Climatic and human–environmental conflicts may have not only been the catalyst for the evolution of HIV as a lethal human pathogen but also the precursor of the human social dynamics that have been so instrumental in the wide propagation across the continent and the globe. For the sake of posterity, social learning should trigger alarm bells when such circumstances coalesce as an early warning signal for new or reemerging diseases. As the famous historian Robin Weiss states, "the red, white and pale horses of the apocalypse representing conflict, famine and pestilence ride well together," it is often forgotten that preceding these three horses was the white horse representing the philosophy of exploitation (New Testament Bible; Book of Revelations, Chapter 6). All efforts now should be aimed at relieving the human exploitative pressure on land and other human beings and mitigate the negative effects of climate change. Improving livelihoods and the well-being of families with adequate nutrition would reduce the likelihood of HIV infection and its complications. While these mitigation and adaptive processes are being implemented, scientists and funding agencies must focus on a definitive cure for HIV/AIDS, which should be delivered and implemented speedily and without prejudice. Eminent historians of health, population, and environment propose that with the spread of communication and advances in science and technology it should not be too difficult to restore the earth to a state of natural harmony and reduce the exponentially rising impact of human populations on the carrying capacity of the earth through a more equitable existence. We should be cognizant of the fact that at the rate we are proceeding if we do not have a strategy by design we may end up with an undesirable culture by default.

GHG Greenhouse gases

Heat exposure The actual thermal environmental (climatic) conditions quantified in a way that indicates the likelihood of heat stress. This variable can be calculated from climatic data (weather station data) or specially measured data. Heat exposure depends on air temperature, humidity, air movement, and any direct heat radiation (outdoors usually from the sun). Measure air temperature and humidity (can be done with cheap dataloggers). Add wind speed and heat radiation if possible, but these can be estimated.

Heat strain Heat strain is the effect on the individual from the heat stress. Heat stress eventually increases core body temperature when heat gain is greater than heat loss. A limited increase in core body temperature and subsequent sweating is part of the normal physiological reaction to heat stress and comprises low and reversible physiological strain. At higher levels of heat stress, the physiological strain on the human body is sufficiently high to create symptoms of excessive noncompensable heat strain eventually leading to hyperthermia, heat collapse, or heat exhaustion. In extreme cases, severe heat stroke and even death occurs. The individual variation in heat strain can be estimated by physiological models that use as input the specific parameters of an individual. Items of importance include age, sex, pregnancy level of dehydration, physical fitness, and degree of obesity.

Heat stress Heat stress is a measure of the environmental influences that alter the heat gained and heat lost by the individual. The heat burden on the individual physiology, which is determined by the level and duration of 'heat exposure,' the persons' physical activity intensity (metabolic rate), and the persons' clothing. Heat stress can be reduced by avoiding direct sunshine, using suitable clothing, or reducing metabolic rate, which for working people means working less intensively and taking more rest breaks. An increase in sweating (except at high humidity) and a limited work regime to prevent an increase of core body temperature are part of the normal physiological reaction to heat stress. Another aspect of heat stress is the extent to which the person is acclimatized to heat. This has a limit, however, and 'behavioral acclimatization' is an important aspect of the

http://dx.doi.org/10.1016/B978-0-12-384703-4.00120-9

actual heat stress on a person. Quantification of heat stress should be based on physiological responses leading to 'rational heat indices.' It should be noted that there are individual variations in the association between heat exposure and heat stress, and statistical averaging is required based on the estimated risk distributions in populations.

IPCC Intergovernmental Panel on Climate Change

ISO International Organization for Standardization

NOAA National Oceanographic and Atmospheric Administration (USA)

UTCI Universal Thermal Climate Index is an indicator of perceived heat stress that takes into account climate variables, clothing, and limited physical activity (set fixed at walking 4 km h^{-1}). Calculation formulas based on weather station data are available on the website utci.org.

WBGT Wet Bulb Globe Temperature is an indicator of heat exposure that incorporates workplace air temperature, air humidity, wind speed (air movement), and both short- and long-wavelength heat radiation on the worker. Special equipment with three thermometers is available (check in Google).

1.12.1 Introduction

People working in hot environments are vulnerable to health effects of heat. The health effects include heat exhaustion, heat stroke (which can be fatal), and increased accidental injury risks in workplaces (Parsons 2003). Populations in large cities experience additional heat exposures because of the 'urban heat island effect' making densely built urban areas several degrees warmer than the surrounding countryside. Increasing air temperatures and/or humidity as part of local climate change would further increase these occupational health risks (Kjellstrom et al., 2009a, b, c).

Daily heat exposure during the hot season in tropical and subtropical parts of the world is a problem particularly for people working in jobs that cannot be, or are not, cooled by air conditioning or other technical methods. Intense physical labor creates substantial surplus heat inside the body, which must be released to avoid health-threatening increased core body temperature. When air temperature exceeds 37 °C, evaporation of sweat becomes the only mechanism to cool the body, but sweat evaporation is strongly impaired by high air humidity. Tropical climates with high humidity are therefore a particular occupational health and safety problem. The current hazards of excessive heat exposure at work in low- and middle-income countries have been referred to in a number of recent publications, and these are summarized in this chapter.

Protective measures include shading, fans, and cooling systems, but these do not protect at high humidity and may not be sufficient or possible to apply in certain jobs. In those situations, the most effective protective method is a reduction of internal heat production by, for example, taking more and longer rest periods during work hours with excessive heat exposure. However, these rest periods reduce hourly productivity and the daily economic output of the workers. Thus, this effect on occupational health and safety is also likely to undermine local economic development.

This chapter presents different methods to measure heat exposure and effects. Regional and global assessments of the impacts of climate conditions on occupational heat exposures and effects in different parts of the world will be presented. There will be practical advice on preventative measures to minimize heat stress and strain as means to adapt to climate conditions, including climate change as modeled by the Intergovernmental Panel on Climate Change (IPCC). Mitigation of climate change (reducing its extent) is not dealt with in detail, but it is, of course, another important means to prevent negative impacts on occupational health and productivity in countries at all income levels, if, as projected, the local heat exposure would increase in many parts of the world.

1.12.2 Current Climate and Ongoing Climate Trends

Many parts of the world, particularly tropical areas, already have climate conditions that are so hot that daily life, particularly for working people, is affected. Heat stress maps for the whole world have been produced by Jendritzky and Tinz (2009), and they show the high heat exposures present now and the trends toward higher exposures in the future.

The authors have used freely available daily weather station data from NOAA in the United States (their website contains daily data from many thousand stations around the world: the Global Summary of the Day, GSOD) to calculate and visualize the annual averages of daily maximum, mean, and minimum temperatures, dew point (an indicator of absolute humidity), wind speed, and rainfall for a number of locations in some of their publications. The graphs in Figure 1 show an example for a city, indicating typical trends of temperatures in cities of tropical and subtropical Asia. It is likely that these trends include significant impact of the 'urban heat island effect' due to urbanization, pointed out by Oke (1973). The figure shows the equations for fitted lines to the recorded data, and it shows that each of the temperature levels have increased by approximately 0.5 °C per decade during this 30-year period.

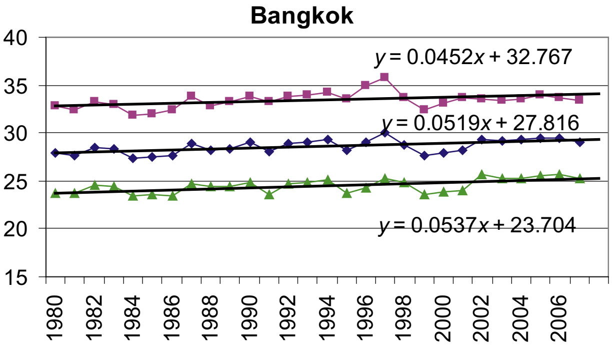

Figure 1 Time trends of annual averages of maximum (pink), mean (blue), and minimum (green) temperatures at Bangkok airport, Thailand.

In this chapter, the term 'climate change' is used as a way to refer to these ongoing changes of air temperature and humidity, as well as the future changes projected via careful modeling by the IPCC. Some people insist on using the term 'climate variability' instead of 'climate change,' but this obscures the notion that climate effects include those caused by human activities that emit greenhouse gases (GHGs) and aerosols, as well as from land-use change (NRC 2005).

In populated areas with extremely cold periods each year in the Northern Hemisphere (including the northern parts of Europe, Alaska, Canada, and Russia), the ongoing trend toward higher average temperatures can also be demonstrated; this will reduce winter cold stress in some occupations but may also increase heat stress in summer. However, clothing and other protective means against cold already reduce cold stress on working people. Cold conditions also induce people to work harder to generate more body heat. It is more difficult to protect workers against extreme heat without expensive and energy-intensive equipment such as air conditioners.

It should also be emphasized that the areas of the world with extreme cold climate are much less populated than the areas with extreme heat. In the Arctic, the population is less than 1 million, while in the tropical areas, the population is approximately 4000 million.

1.12.3 Different Occupational Health Effects of Climate Variables

Climate conditions, and particularly trends toward hotter environments, do affect various aspects of occupational health and safety as highlighted by Bennet and McMichael (2010). A few are listed here.

1.12.3.1 Extreme Weather Events

As concluded in the 2007 IPCC report, more energy absorbed and maintained in the atmosphere should increase the likelihood of extreme weather events: for example, hurricanes, tornadoes, typhoons, storms and rainstorms leading to flooding, and lack of rain leading to drought (see Chapter 2.1 of this book). Such conditions lead to injuries and other health risks for emergency workers, and the local affected populations may be injured and lose essential services, which increases health risks and has negative economic effects.

1.12.3.2 Occupational Heat Stress

This is the most direct effect of climate conditions, and this health hazard has been analyzed in detail by Parsons (2003). High air temperatures, especially in combination with high humidity, create physiological challenges and risks of heat exhaustion, heat stroke, and even death. The most extreme impacts of heat-related deaths during work are occurring even in developed countries like the United States as reported by the Centers for Disease Control (CDC) and the mortality and morbidity weekly record (MMWR 2008). This hazard is described in more detail below, and the reference list contains the main evidence relating to climate trends. There are also heat morbidity and mortality risks in the general population. At the other end of the climate spectrum, cold stress is a serious health hazard, which in areas with extremely cold winters may become less common if the local climate gets warmer.

1.12.3.3 Kidney Disease due to Daily Dehydration

Workers who are exposed to high heat levels while carrying out heavy labor lose large amounts of liquid via sweating each day: $1\ \mathrm{l\ h^{-1}}$ or even more can be sweated in such conditions. During a work-shift, the lost liquid may be 10 l or more, and if this liquid is not replaced by drinking water the worker develops dehydration. If as little as 2–3 l of lost liquid per day is not replenished the dehydration may lead to clinical symptoms of fatigue and related losses of work capacity. If dehydration occurs every day during long work periods, it is possible that clinical damage to the kidneys can occur. This could be one explanation for an epidemic of chronic kidney diseases currently occurring among sugar cane cutters in El Salvador and Nicaragua.

1.12.3.4 Increased Chemical Exposures

Many workplaces are using chemicals that evaporate at room temperature and create inhalation exposures in the workers. Of particular concern are the widely used organic solvents, as increased temperature of liquid chemicals increases the speed of evaporation of the chemical, leading to higher concentrations in the air at the place where the chemical is used. The absorption of these chemicals, especially the hydrophilic ones, is very high during high-heat situations and metabolic workload. The impact of these chemicals on workers working in different temperatures varies and hence the safety limits. Often the threshold limit values (TLVs) for such chemicals cannot be achieved universally for all occupational settings. This occupational health aspect of climate conditions has received almost no attention in research or analysis so far.

1.12.3.5 Vector-Borne Diseases

Some vector-borne diseases, spread by mosquitoes, are likely to be a particular problem for agricultural workers in hot locations. These diseases include malaria and dengue fever, and the climate connections are presented in a number of review publications, e.g., by Costello et al. (2009) and McMichael et al. (2003, 2004). If the daytime periods get so hot that only limited work can be carried out, the agricultural workers may spend more time working in the early mornings and late afternoons when the mosquitoes are the most active in biting humans. Thus, the risk of getting these diseases is likely to increase as the climate gets hotter, and the need for preventive measures increases.

1.12.3.6 Ecological Change Diseases

Climate change, in the form of increased temperatures of air, surface water, and soil and/or greater or lesser rainfall and air humidity, can be associated with ecological change that can create new health risks for working people. If the ecology changes locally, disease vectors or infectious agents (bacteria, viruses, and parasites) may spread to new areas and at different seasons than what is common currently. This will expose working populations to risks that they have been spared in the past. One example is the schistosomiasis parasite that spreads via snails in waterways (rivers, dams, canals, and rice fields). In China, these snails cannot survive in large areas of the country because the coldest periods are too cold. As the climate gets hotter and water temperatures in many waterways increase, the snails spread to new areas, and the risk for infection among local farming and fishing populations increase. It has been estimated that the expansion of the geographic area where this disease occurs in China as climate is changing will put many million people at risk. Occupational groups working in forestry and agriculture are exposed to new types of hazards that are not well understood, e.g., new species or new strains of vectors that the existing health system is unprepared to tackle.

1.12.3.7 Infectious Diseases

Diarrheal diseases are more common in areas with periods of high temperatures, as bacteria in foodstuffs can multiply faster when temperatures go up. In addition, higher temperatures in surface waters create greater risk of bacteria and virus contamination of drinking water. This is a problem for whole communities, and children are in general the most affected. However, working people may be at particular risk as they bring foodstuffs to work for consumption during lunch, and spaces for keeping the foodstuffs cool are not available. Of course, these health risks, just like the others mentioned earlier, are more likely to affect poor people without the ability to use protective methods. These problems have been described in Chapters 3.2 and 3.3 in this book.

1.12.3.8 Nutritional Security

Agriculture is naturally dependent on the local climate conditions. As climate is changing, leading to hotter temperatures in tropical areas and/or major changes in rainwater access, some places will have great problems maintaining local agricultural productivity that the local poor populations depend on. Extensive drought is already a problem in parts of Africa and Asia, and this leads to reduced access to food in the local populations. The main serious health problems are usually recorded among preschool children, but it is likely that working adults also get affected by lack of sufficient nutrition. This type of effect would not normally be included in the analysis of occupational health problems, but it is one feature of climate change that may become of great importance in some parts of the world. The increasing temperatures in very cold areas of the world are likely to increase agricultural productivity in those places (e.g., Canada and Russia), but this impact does not help poor working people in tropical areas.

1.12.3.9 Social Tensions: Mental Health

Another feature of climate and health that is of great importance in some communities is the social and mental stress associated with, for instance, local agricultural productivity. In Australia, it has already been reported that the incidence of suicides among farmers affected by long-term drought has increased. Similar stories emerge from India. The undermining of the livability in certain parts of the world because of local climate change has already led to 'climate refugees' abandoning places they used to live in and moving to other places. The mental and social stress for the refugees themselves and the communities of places they move to is becoming an increasing concern for international development agencies. Again, this is an effect on working peoples' health and livelihood that is seldom considered as a part of occupational health. The impacts of occupational heat stress also spill over to the families of the workers, as increased incidence of violence and unrest have been reported in studies of this concern.

It should be pointed out that working people are also affected by heat exposures outside of work. If hot temperatures impair the quality and/or quantity of the nightly sleep, this will decrease work capacity on the following day. In some jobs, commuting to and from work involves very high heat exposures. In addition, if heat prevention involves long breaks (siestas) in the middle of the hot days, and work very early in the morning as well as into the evening, the effect on family social connections may be very disruptive. High temperature and humidity also create mold problems in dwellings, with risks for allergies and fungal diseases. Thus, it is not just increasing heat exposures at work that can become a problem for working people if the climate is changing. Of course, air conditioning in residences and workplaces are becoming more and more common, but the energy cost is prohibitive for many people, and regular electricity cuts ('brown outs') reduce the cooling outcomes in many places.

As mentioned earlier, poor people in localities with extreme climates and climate that is heating up are the most likely to be affected by these work-related health and well-being hazards. Among working people, one can also identify a number of vulnerable groups:

- People working in heavy labor in tropical and subtropical countries during the hot season, particularly if their work has to be done in hot sunlight
- Workers who need to work continuously at high physical intensity
- Workers who need to wear heavy or impermeable protective garments
- Agricultural workers
- Construction workers
- Emergency workers
- People in vulnerable positions, for instance migrant workers
- Workers in factories or workshops without efficient cooling systems; a common situation in low- to middle-income countries
- Workers in slum workshops

1.12.4 Excessive Heat Exposure as a Special Occupational Health Hazard

The mechanisms of heat gain and loss by the human body are well understood and have been reviewed by Parsons and others. The main mechanism of heat gain is the heat generated by muscles that work at approximately 20% efficiency. Heat can be transferred to/from the body by convection, conduction, radiation, and evaporation of water (sweat). Air is a very poor conductor of heat, so the significant heat transfer mechanisms (unless submerged in water) are convection, radiation, and evaporation. Environmental factors that influence these heat transfer mechanisms are air temperature, wind speed, humidity, and radiation sources.

Heat gain = Heat loss + increase in stored heat. The increase in stored heat is reflected by a rise in core body temperature. While some increase in core temperature above 38 °C is acceptable, conditions where heat gain is greater than heat loss for prolonged periods lead to an increase in core temperature that is incompatible with healthy life. There is debate concerning the actual value of this critical core temperature (in the range 38–39 °C), and it varies from person to person, with ethnic groups, with age, with gender, and with the number of days at high heat exposure.

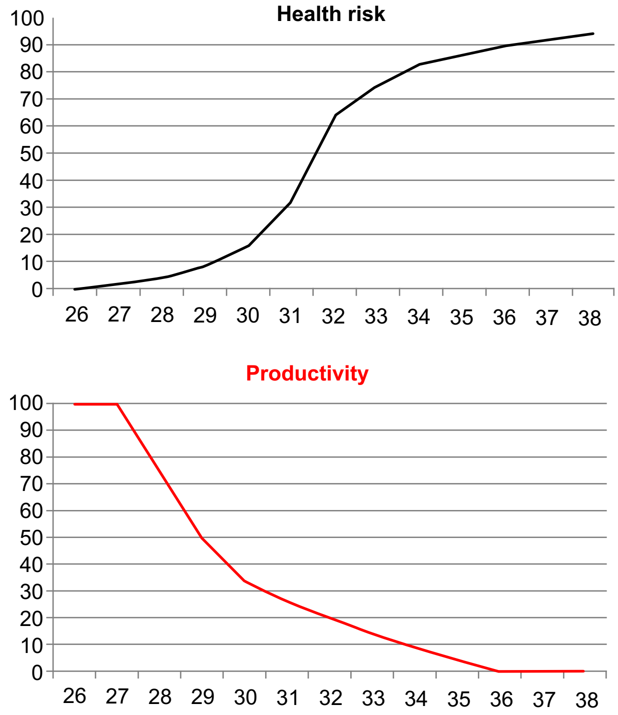
The ability of an individual to lose heat also depends on the degree of acclimatization, the number and activity of sweat glands, the cardiac output, the amount of blood able to be redirected to the skin for cooling, the degree of hydration, the surface area of the skin, and the clothes they are wearing.

If one is measuring the heat strain of an individual, all these factors must be taken into consideration. However, when giving advice to groups of people on the risk of heat stress, or researching the effects of climate conditions on heat stress, it is more useful to have a heat stress index that depends only on environmental variables. The wet bulb globe temperature (WBGT) is the most widely used index of this type and is used in national and international standards for recommended maximum workplace heat exposure (e.g., International Organization for Standardization (ISO) standards). Such recommended levels vary between countries and may be lower in cool countries (e.g., England) with occasional hot spells than in hot countries (e.g., India) where the population is more acclimatized and better adapted to higher temperatures. Using heat stress indicators helps the regulators or concerned authorities to predict the conditions based on weather forecasts and to be prepared for protection of the workers.

1.12.5 Occupational Health and Productivity Effects of Heat Exposures

The links between human physiology, climate conditions, and effects on health and work capacity have been discussed in detail in physiology and ergonomics texts, e.g., by Parsons (2003) and Bridger (2003). High heat exposure creates a risk of heat exhaustion and heat stroke and is subjectively perceived as unpleasant or dangerous. People working or involved in heavy physical activity are particularly affected as highlighted in the authors' publications (see References and Proposed Additional Reading), because physical activity produces additional heat in the body. A natural reaction of a working person to heat is to reduce physical activity, which reduces the body's internal heat production. An outcome of this preventive reaction is reduced hourly work capacity and reduced economic productivity during exposure to heat. Thus, the balance between health risk that increases with heat exposure level and maintaining productivity is an issue that creates occupational health problems of a difficult kind (Figure 2).

An enterprise can compensate for this heat effect by carrying out heat-sensitive work during the cooler night hours of the hot season or by scheduling such work into the cooler season, but if heating climate trends progress, the duration of 'cool periods' will diminish in many parts of the world. In addition, some work has to be carried out during daylight, which reduces the available



If WBGT goes up and the worker does not reduce physical labor output, productivity goes down somewhat, while heavy physical labor continues, and the risk of serious health risk (e.g., heat stroke) goes up.

If WBGT goes up and the worker reduces physical labor in accordance with occupational health standards, the productivity will go down substantially but the health risk will stay relatively low. Thus, the workers' action to preventive ill health results in lower productivity

Figure 2 The 'competition' between increasing health risk and increasing productivity loss due to workplace heat. Source: Kjellstrom, T., B. Lemke, and O. Hyatt, 2011: Increased workplace heat exposure due to climate change: a potential threat to occupational health, worker productivity and local economic development in Asia and the Pacific region. *Asian-Pacific Newslett. Occup. Health Safety*, **18,** 6–11.

'cool hours.' For instance, many agricultural workers need to work outdoors in the sun, and if their pay is based on their product output, they may work beyond safe heat exposure limits and die of heat stroke, even in the United States, as reported by CDC, MMWR (2008). If a worker chooses to work, the number of hours the worker can work safely without any physiological impact reduces, thereby reducing income and the economic performance of the community. The mechanisms behind the health and productivity effects of heat, and the relationships to climate change, have been described in some detail in recent reports available for free on the web (see Global Health Action 2009, 2010) and will not be repeated here.

1.12.6 Measuring Heat Stress and Strain

Measuring the effects of heat stress on humans has many perspectives. For health and safety issues: the effect of heat stress on an individual undertaking a particular activity. For forecasting purposes: the effect of heat stress on the people in a particular location (such as a city). For long-term impacts of a hotter climate: the effect of heat stress on the population of the world.

Measurement of heat-related health risks fall into two categories: heat stress and heat strain as highlighted in the Glossary. Conventional engineering terminology defines stress as external forces and strain as the response by the object or individual to those stresses. As such, heat stress is a measure of the environmental influences that alter the heat gained and heat lost by the individual. Heat strain is the effect on the individual from the heat stress. This is very dependent on the individual, where they live, what they do, and what they wear. It can be altered by working less hard, moving to a cooler location, changing clothing, shading, fanning, and cooling down in water.

If the quantity of individual heat strain is required to be known, physiological models exist in ISO standards to calculate heat strain. These include the required sweat rate model, the Physiological Heat Strain (PHS) model by Malchaire (2006), the US Air Force model, and the Fiala et al. (2001) model.

While there are numerous indexes to quantify heat stress (as highlighted by Parsons (2003)), the authors focus on WBGT because this is the best developed index for workplace applications with rest/work cycles clearly specified under different work conditions. The heat stress standards at both national and international levels indicate that for people working in heavy labor a WBGT level above 26 °C requires hourly rest periods away from the heat to avoid core body temperatures rising to a dangerous level. For lighter labor, like inside a factory, the threshold for rest periods is at 29 °C.

If one documents an increasing trend of calculated WBGT (indoors in the afternoon) in a location, it is a sign of climate variability and can also be a sign of ongoing climate change on top of the variability. The authors used routine local weather station data with new software, designed by their team, to display the climate trends. Figure 3 shows the situation for a major city in the eastern part of Thailand: the number of days each year when calculated indoor WBGT in the afternoon is above 29 °C. This is the upper 'tail end' of the local heat situation, but it gives a vivid picture of the number of days when work productivity can be affected by increased rest periods, or when heat stroke health risks are increased if the workers do not take breaks. There is a great variability from year to year, depending on underlying weather variations (possibly due to the El Nino–Southern Oscillation (ENSO) annual impacts). However, if a line is fitted to the data, (Figure 3), the general trend is an increase of extreme heat stress days from approximately 60 per year in 1980 to approximately 110 per year in 2011. Thus, the annual period of extremely hot days for working people has lengthened by a month during these 32 years.

1.12.7 Occupational Health Standards and Guidelines

The WBGT index includes the impacts on three thermometers from four environmental climate factors (temperature, humidity, air movement, and solar radiation) and so does not depend on individual differences. The ISO standard used in conjunction with WBGT then relates the WBGT level allowable for different clothes, different levels of work, and other individual characteristics.

The heat strain is addressed by the ISO (1989) and national standards that outline the conditions to minimize the effects

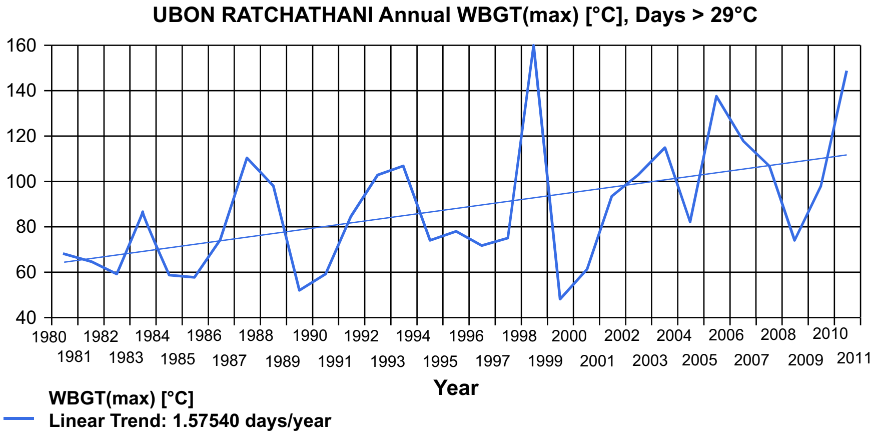


Figure 3 Number of days each year when calculated WBGT indoors in the afternoons (the hottest part of the day) exceeds 29 °C in the city of Ubon-Ratchathani, Thailand.

on the individual. The ISO uses WBGT to recommend maximum hourly limits for work in hot environments in order to ensure that average core body temperature of workers is not higher than 38 °C. Many countries have national standards for heat strain at work that gives organizations a guide to what precautions to take when the heat stress reaches a certain point.

The ISO standard identifies maximum WBGT levels for continuous work (hourly), 25% rest during a work hour, 50% rest, and 75% rest, which can be used to analyze the reduction of hourly physical work capacity as WBGT increases. These standards are based not on average responses to heat stress but on the response of the most vulnerable 5–10% of the population, as it is undesirable to have anyone suffering from the effects of heat strain. Part of the action plan once the heat stress gets above a certain point (TLV) is to make more detailed heat strain measurements on individuals to ascertain whether an individual is suffering from heat stress or not.

The WBGT index was developed after detailed studies by US military ergonomists in the 1950s. While WBGT has been criticized by Budd (2008) and others, it has all the correct components to indicate physiological heat stress. One criticism of WBGT is that it is too stringent for determining conditions when full workload should be reduced. This criticism has less to do with the WBGT index than the ISO standard criteria for reduction of workload. For instance, Nag et al. (2009a,b) considered that an increase in core body temperature up to 39 °C was acceptable or tolerable, while ISO limits the increase to 38 °C. The risk of heat stroke increases with an increasing core body temperature, so the 'margin of safety' will be less if 39 °C is used as compared to 38 °C. It all depends on how much discomfort and health risk is regarded as 'acceptable.' The ISO standard is currently being updated in order to address some of these criticisms.

New heat stress indexes such as the Universal Thermal Climate Index (UTCI) are based on the heat balance mechanisms of the human body. They are difficult to use at the workplace because conditions vary all the time: People change their clothes, clouds pass over, different movement creates different apparent wind speed, and walking and bending over expose different body profiles to the sun. This continuously changes the mean radiant temperature and air movement experienced by the worker – two key components for the UTCI calculation. Further, little research has been published for this new 'rational' heat index in relation to work/rest cycles to prevent excessive increases in core temperature in the majority of workers at a workplace.

Mathematical formulas to calculate WBGT and UTCI based on weather station data have been published. The authors recommend the Liljegren or Gaspar methods for outdoor WBGT and the Bernard method for indoor WBGT (Liljegren et al. 2008; Gaspar and Quintela 2009; Bernard and Pourmoghani 1999). Unfortunately, some formulas available over the Web are incorrect and should be avoided. In calculations of indoor WBGT the authors assume a wind speed of 1 m s^{-1}, as this would represent the speed at which arms and/or legs would be moving through the air for a worker carrying out physical labor. For indoor calculations, one can assume that solar heat radiation is not present.

1.12.8 Reported Experiences of Workplace Heat Exposures and Effects

A number of recent publications in the journal *Global Health Action* have described the heat stress experiences of working people in several countries. It is clear that in many jobs people are used to take preventive actions, such as refraining from working during the hot afternoons (aka siesta) or replacing heavy labor jobs in hot environments with robots or other technological solutions.

It is surprising, however, that quantitative estimates of the exposure–response relationships between heat exposure and health risks or work productivity losses have received little research attention during the last 50 years. In the 1950s and early 1960s, Dr Wyndham in South Africa published a large number of reports on the heat effects on gold mine workers. Table 1 shows how the heat effect risks increase as the estimated level of heat exposure increases. The research was aimed at finding ways to reduce the serious clinical health effects of heat (including deaths) at mine depths of 1 km. One reason for fatalities was the time it took to take a worker out from the mine if he developed heat stroke symptoms. Dr Wyndham developed and tested an 'acclimatization chamber' at ground level, and new workers were exposed to heat similar to that found underground while doing strenuous exercise at similar metabolic rates as needed for the work underground. The exposure in these chambers continued for 2 weeks, and the percentage of new recruits who could cope with the heavy labor at the high heat exposures increased from 14 to 29%. This indicated the acclimatization that was achieved in some workers, but it should be stressed that even after the chamber exposure for 2 weeks, 71% of the new recruits could not cope with the heaviest underground working conditions. Dr Wyndham's studies also included analysis of productivity

Table 1 Heat effects on gold mine workers in South Africa in the 1950s and 1960s

WBT, °C	*Approximate number of workers*	*Nonfatal heat stroke rates per million workers per year*	*Fatal heat stroke rates per million workers per year*	*Loss of work productivity, percentage of hourly output*
< 27	371 318	1.6	0	0
27	177 960	6.7	0	2
30	178 536	49	17	15
32	89 113	139	36	32
33.5	15 507	320	114	45
35	1800	889	666	60

Wet bulb temperature (WBT) levels of heat exposure are similar to WBGT levels; data from a 6-year period (Based on data in Wyndham, C. H., 1969: Adaptation to heat and cold. *Env. Res.*, 2, 442–469.).

Table 2 Summary of heat-related health effects and productivity losses in industries in southern India

Type of industry	*Employees with health effects (%)*	*Employees reporting productivity loss (%)*	*Managers reporting productivity loss (%)*	*Safety expenditure due to heat stress (%)*
Auto manufacturing	44	29	17	54
Chemical manufacturing	65	60	8	4
Hotel industry	86	44	73	14
Construction industry	92	90	68	50
Support services in healthcare industry	67	38	40	20

Venugopal, personal communication.

losses at different heat exposure levels (Table 1). It is not clearly stated in the reports, but one can assume that only the workers who passed the ‘acclimatization test’ were sent underground for daily work. These are the most quantitative estimates of heat health risks in real workplaces that have been published. It must be borne in mind that in spite of acclimatization and adaptation to changing climatic conditions, the human body can perform only within certain limits, beyond which it is accompanied by physiological decrements and productivity losses. There is a great need for further quantitative studies of heat effects.

A more recent example is the data collected in factories in South India during studies in 2011 (Table 2). The studies cover heat measurements and interviews with workers and supervisors representing hundreds of workers in the types of factories listed. The prevalence of heat-related health effects is very high in some industries, and productivity loss is a common issue reported by both workers and managers. Additional workforce is employed to achieve the company’s productivity targets, which impacts the industry’s budget directly. Indirect expenses include training costs, especially in outdoor occupational sectors, where there is a high turnover of the workers during summer months when the workers are not able to cope with the workload and the high ambient temperatures. It is also interesting to note that in some industries a large proportion of the safety expenditure is related to reducing heat exposures and effects during summer months.

Additional examples from India have been provided by Ayyappan et al. (2009), Balakrishnan et al. (2010), and others, and examples from Thailand, Taiwan, South Africa, Cameroon, Nicaragua, Costa Rica, and other countries are given in *Global Health Action*.

1.12.9 Estimated Impacts on Occupational Health of a Subset of Projected Future Climate Change with Increasing Heat Exposures

As mentioned earlier, many places in tropical or subtropical countries already have daily maximum heat exposures higher than levels interfering with work productivity and health protection at work. Projections into the future further emphasize the heat impact risks that could develop. Figure 4 shows as an example of one of the hottest months in Asia and the IPCC model projections from 1975 to 2050 of increased indoor WBGT levels in the afternoons. Parts of Pakistan and Northern India are projected, based on the IPCC modeling, to be so hot that any kind of physical work will become physiologically impossible. It should be pointed out that mental work is also affected by high heat exposures as described in studies by Hancock et al. (2007).

Large parts of Asia, including densely populated areas in India, China, and Southeast Asia, will have afternoon indoor WBGT levels above 30 °C, which will significantly reduce hourly work capacity. The exposures presented in Figure 4 are monthly averages; so individual days will be even hotter. In addition, it should be pointed out that outdoor heat exposures in the afternoon sun may have approximately 3 °C higher WBGT values, which indicates major heat stress for workers in agriculture, construction, and so on.

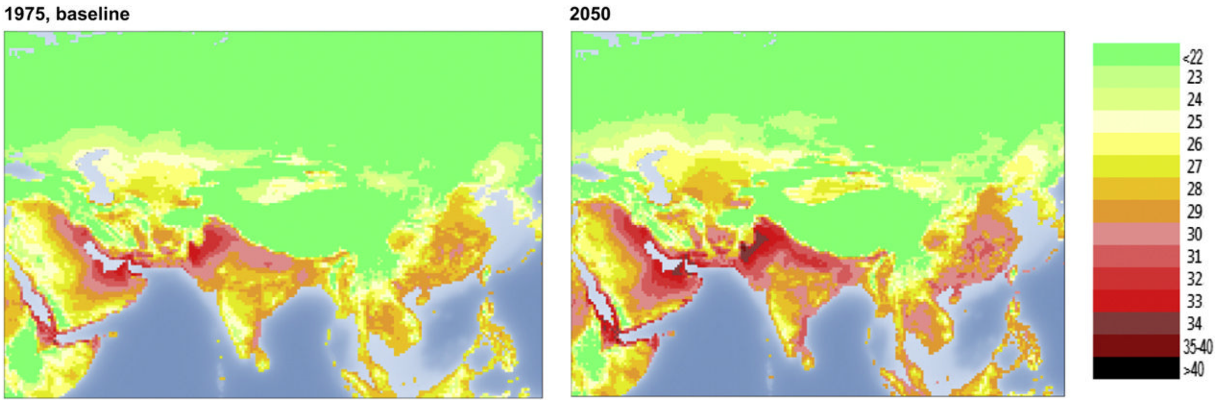

Figure 4 Global grid cell (0.5 × 0.5°) based maps of averages of daily maximum WBGT levels indoors during July in Asia in 1975 and predicted for 2050 (based on the BCM climate model). The color scale indicates the WBGT levels.

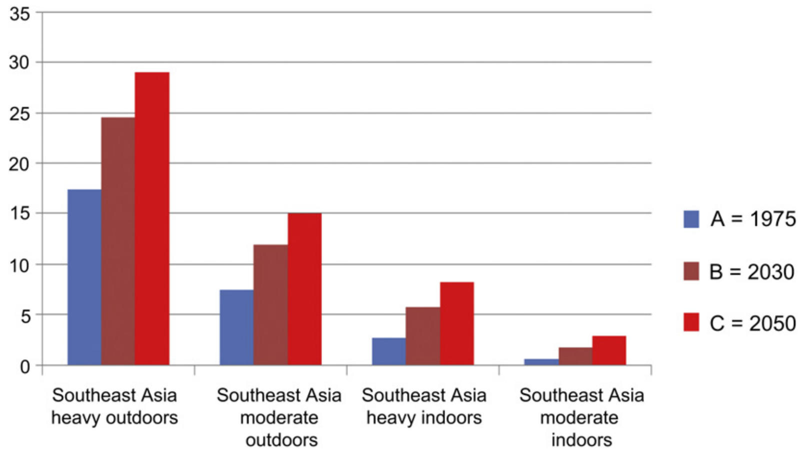

Figure 5 Percentage of annual work capacity loss in moderate–heavy physical work due to workplace heat exposure, Southeast Asia, based on climate model outputs for 2030 and 2050 (based on the BCM climate model).

The authors' research team is working on detailed assessments of workplace heat exposures using this type of modeling outputs and is estimating the impacts on different occupations. If each daylight working hour in a year is assigned with a specific WBGT exposure level, one can calculate the impact depending on the degree of physical activity in different jobs and whether they are carried out indoors or outdoors. Figure 5 shows the result for Southeast Asia. In heavy outdoor work, the loss of work capacity (expressed as percentage of all daylight work hours lost per year) in the 1975 climate was 17%, which then increases to 24 and 29% in 2030 and 2050, respectively. The losses in moderate outdoor work or heavy and moderate indoor work are less, but the trends with the projected increase of excessive heat days go in the same direction. The next step would be to estimate the related economic losses, but this has yet to be done.

When these methods are applied to a region using the grid cell heat exposure change and working age population within each grid cell, one can calculate the occupational heat stress impacts at a regional level. An example for East Asia (mainly China), with an estimated working age population at 768 million in 2050, is shown in Table 3. These calculations were made with three different climate change models recommended by WHO [BCM (Bergen Climate Model, from Bergen University, Norway), EGMAM (ECHO-G^2 with Middle Atmosphere and Messy interface climate model, from Free University Berlin, Germany), and IPCM (Institute Pierre Simone Laplace -Climate Model, from Institute PSL, France)], and the table shows baseline values for 1975 (actually the average of 1961–90) as well as the 2050 exposure and impact results.

Table 3 indicates which impacts can be expected if the climate becomes hotter. The exposure change is indicated by the percentage of grid cell person months when WBGTmax (in the afternoons) is greater than 26 °C. Then come clinical effect risks per million working people and the percentage work capacity loss per working person (based on loss of daylight work hours). By applying the size of the working population in 2050, one can also calculate the estimated number of sick cases and work hours lost. The details will not be repeated in the text here, but it is clear that a high percentage of loss in work capacity and millions of work hours lost in the population will have economic and social consequences for families, communities, and whole nations. Preliminary findings of our studies in India show that workers spend about 2–8% of their income on heat-related issues, including medical expenses, adapting to changing climate, and protecting themselves from the impacts of heat stress.

1.12.10 Methods to Reduce Heat Exposures and Effects

There are good descriptions of heat prevention approaches in reports by Parsons. The special challenge is of course that the prevention of health risks in many work situations creates loss of work capacity and work productivity.

Mitigation of climate change is therefore an important way to reduce the increase in heat exposures in workplaces and the related occupational health risks. However, good natural ventilation inside workplaces and, when necessary, air conditioning can make a big positive difference. The focus should also be on strengthening and improving the local occupational health management programs in collaboration with the workers themselves. This would be in line with international recommendations and standards. Free access to clean drinking water is a major requirement in jobs that are associated with heavy sweating. This would prevent dehydration, which is a serious health and performance risk.

When planning and building new workplaces, whether factories or other work situations, it is important to consider the design to reduce future excessive heat exposures. Keeping trees or other creators of shade around a workplace is important, as well as architectural methods that reduce overheating of the roof or walls. Black roofs are particularly bad as they absorb and transfer solar heat indoors, and an effective heat-reduction design can include two roof layers with air or other insulation in between. Natural cooling systems inside buildings can also be designed to reduce local heat stress. Any heat emitting part of the factory engineering facilities should be located in a place isolated from the workers.

Table 3 Listing of all predicted occupational heat stress impacts in 2050 in East Asian region (based on the BCM climate model)

Variable	*Baseline (1975) (A)*	*BCM*	*EGMAM*	*IPCM*	*Average of the three models (B)*	*Difference B−A*	*Ratio B/A*
Fraction of all grid cell person-months of heat exposure when WBGTmax >26° C (%)							
	12.3	18.3	19.2	21.4	19.6	7.3	1.6
Clinical effect risks, heat strokes, per million working people							
Fatal heat strokes, outdoor	3.4	6.3	7.8	10.1	8.1	4.7	2.4
Fatal heat strokes, indoor	0.03	0.8	1.6	2.2	1.53	1.50	50
Nonfatal strokes, outdoor	12.0	22.3	27.4	33.6	27.8	15.8	2.3
Nonfatal strokes, indoor	1.1	3.9	6.0	8.0	6.0	4.9	5.5
Work capacity loss of daylight work hours per working person (%)							
Heavy labor, outdoor	3.65	6.26	7.21	8.45	7.31	3.66	2.0
Heavy labor, indoor	0.59	1.54	2.10	2.69	2.11	1.52	3.6
Moderate labor, outdoor	1.6	3.0	3.7	4.5	3.77	2.17	2.4
Moderate labor, indoor	0.2	0.5	0.8	1.0	0.78	0.58	3.9
Light labor, outdoor	0.34	0.91	1.25	1.62	1.26	0.92	3.7
Light labor, indoor	0.001	0.04	0.09	0.17	0.10	0.10	100
Annual clinical cases based on workforce distribution and exposures							
Fatal heat strokes, outdoor	629	1166	1444	1869	1499	870	
Fatal heat strokes, indoor	10	259	517	711	495	485

Working age population in 2050 is estimated at 768 million. Workforce distribution and exposures: agriculture, 24.1% (heavy labor, outdoor); industry, 42.1% (moderate labor, indoor); services, 33.8% (not affected).

Industries that are already operating should have budgets to have engineering controls, including providing mechanical aids for material handling – dollies, carts, lifting devices – to reduce physical activity need. As part of administrative controls, the health and safety policy should be geared to protecting the workers by training, awareness about the signs and symptoms of heat stress, and job rotation for hot environments and strenuous work.

Personal protection devices with local cool air fans, cooling vests, or other methods for personal cooling should also be considered, but in some situations the only feasible way to avoid overheating is to schedule sufficient rest periods in a cooler space. In some countries, thresholds for maximum heat at work are applied and workers can stop working while their pay is continued, as agreed between trade unions and employers (e.g., in Australia).

It should also be emphasized that this area of occupational health still requires more attention in research and development activities. The global Hothaps program aims at creating more evidence within many countries, in order to raise awareness and create local examples of how the increasing workplace heat exposure problems can be managed. In this sense, research becomes a part of the prevention efforts.

1.12.11 Conclusions

Climate variables are well-known hazards in occupational health, and the increasing heat levels that climate change on top of climate variability is projected by the IPCC to bring about are very important to consider in local, national, and global health programs. By using the WBGT level as the heat indicator, not only temperature but also other climate variables are incorporated into the analysis. Humidity is of particular importance.

This chapter indicates that there are a number of climate-related occupational health and work productivity concerns that can become of great importance depending on the location of workplaces. The most direct impacts are due to occupational heat stress. The authors' analysis indicates that such stress will become an increasing problem, primarily in tropical and subtropical areas. Research and analysis on vulnerability to increasing heat exposure as a result of anthropogenic climate change on top of natural climate variability need to take this part of the health risk panorama into account.

1.13.1 Introduction

It has long been observed that many diseases exhibit seasonal variations and that the characteristics of climate may give rise to some of these patterns. Many parts of the world currently experience higher rates of mortality and morbidity during winter months than during the summer (Wyndham and Fellingham 1978). Part of this wintertime excess can be attributed to seasonal infections such as influenza, but epidemiologic studies have demonstrated that the biggest contribution is made by the explicit effects of exposure to low ambient temperatures (Wilkinson et al. 2004). In most cases, very few of these impacts will be as a direct result of hypothermia, but rather due to cardiovascular and respiratory problems (Goodwin 2007).

This chapter reviews physiologic and epidemiologic evidence of the health effects of wintertime weather. It identifies individual and contextual-level risk factors that heighten vulnerability to cold and provides evidence of adaptation measures that help to minimize impacts. The implications of current and future cold impacts for public health policy are also discussed.

1.13.1.1 Historical Context

Humans have a long history coping with wintertime weather. The period between the fourteenth and the nineteenth centuries became known as the Little Ice Age in Europe because of the severity of the climate. In England, frost fairs were often held on the river Thames in London because it froze over in very harsh winters. During the Great Frost of 1683–84, the worst frost recorded in England, the Thames was completely frozen for 2 months (Appleby 1980).

Historically, exposure to cold weather has been of much public and research interest because of the high wintertime burden on public health experienced in many countries and the annual pressures this places on the usage of health services. Studies conducted as far back as the nineteenth century have identified a detrimental effect of cold weather on human health (Farr 1885). The particular role of low temperatures was demonstrated using a variety of health end points throughout the early part of the twentieth century (Russell 1928; Holland et al. 1961; Loudon 1964). The most recent epidemiologic studies use powerful analytic techniques originally developed for air pollution epidemiology to disentangle the explicit effects of ambient temperature from circulating infections and other seasonal factors. Although there is evidence that adverse cold-related health impacts have been decreasing over many decades because of improvements in housing, better health care, and other factors (Carson et al. 2006; Barnett 2007; Donaldson and Keatinge 1997), the winter excess still remains high in many countries. Recent global increases in fuel prices are also likely to impact negatively on people's ability to warm their homes sufficiently during cold weather.

1.13.2 Cold-Related Health

1.13.2.1 Physiological Effects of Cold

When challenged by cold, the human body focuses on maintaining vital organs. The first response to cold is vasoconstriction,

http://dx.doi.org/10.1016/B978-0-12-384703-4.00121-0

in which blood flow is reduced in the skin and extremities so as to reduce heat loss to the air and keep vital organs warm and oxygenated. Continued cooling induces muscle contractions, shivering, and rapid breathing. Cold air in the lungs may cause the bronchioles to constrict; the heart rate slows, but may increase in those with chronic heart disease.

Less than 1% of cold deaths are caused by a drop in core body temperature (hypothermia) (Collins 1987), whereas the bulk of cold deaths are due to stress to the body of maintaining core body temperature at less than the optimal indoor or outdoor temperatures, and subsequent cardiac and cerebrovascular responses. The difference in etiology is evidenced by the lagged effect of temperature, that is, deaths continue to occur in the days following a drop in outdoor temperature rather than only on the day the temperature drops. It has been reported that coronary deaths are at their highest a few days after exposure to cold weather, whereas respiratory deaths peak about 2 weeks following initial exposure (Keatinge 2002). Prolonged or chronic lower level cold stress causes an immune and inflammatory response. The blood pressure increases, along with fibrinogen, cholesterol, and platelet levels and red and white blood cell counts. Lung inflammation from cold air, possibly compounded by increased virus survival at cold temperatures, increases the risk of contracting respiratory infection (Maheswaran et al. 2004).

Table 1 summarizes the time course of physiologic responses to cold weather exposure.

1.13.2.2 Epidemiology Studies of Cold-Related Health

Epidemiology studies generally quantify two different measures of cold-related health. The first relates to assessment of the seasonal distribution of health events, and an excess winter effect is obtained by measuring the number of health events occurring in the winter months compared to at other times of the year. The second type quantifies the explicit effect of weather factors (mainly ambient temperature) by assessing changes in the daily number of health events in relation to day-to-day fluctuations in the weather. These studies are usually based on regression analysis of daily time-series data, or similar case-crossover designs, and only allow for assessment of acute effects (a few days or weeks) of cold weather exposure.

There are many more studies of the effects of cold, or winter season, on mortality than on morbidity outcomes, in part because mortality statistics are routinely collected in most countries. Descriptive studies of particular diseases sometimes report seasonal incidence – but only as incidental findings not usually discussed in the context of temperature-related health. The difference in all-cause hospitalization rates between different temperatures or seasons is smaller than with mortality. Within disease categories, some conditions can have a winter excess for mortality but a nonwinter excess for hospitalizations. For example, work from New Zealand showed that hospital admission rates for digestive conditions (ICD 10, Chapter 11) were lower in winter than during other months, but death rates were higher in winter (Telfar Barnard 2010). In other disease categories, the winter burden also varies: the excess winter index for circulatory illness (ICD 10, Chapter 9) is higher for deaths than for hospitalizations, while for respiratory disease, the index is higher for hospitalizations than for death.

Some studies also assess more indirect processes of cold exposure, for example, falls in the elderly are more common in the winter, not only because of winter injury hazards such as ice (Bulajic-Koplar 2000) but also because coordination is impaired by cold-reduced circulation.

1.13.2.2.1 Seasonal Distribution of Health Events

In most countries, mortality and morbidity rates are highest during the winter months. Some of this can be attributed to

Table 1 Immediate and delayed physiologic responses to cold exposure

Exposure/period	*Immediate*	*Hours*	*Days/weeks*	*Months*
Moderate cold exposure	Moderate vasoconstriction Increased blood pressure Can cause circulatory illness or death in those with compromised circulatory system	Reduced lung function, as measured by FEV_1 Lung inflammation Suppressed immune responses Can trigger asthma attacks, increases susceptibility to respiratory illness	Increased cholesterol Increased fibrinogen Increased white and red blood cell counts Increased platelet levels Further increased blood pressure More time indoors; if with other people increases exposure to infectious diseases	Decreased vitamin D levels Seasonal dietary changes may also reduce vitamin C
Extreme cold exposure	Vasoconstriction Muscle contractions Shivering Reduced heart rate in healthy adults, possible increase in heart rate among those with chronic heart disease Tacypnea (rapid breathing) Bronchoconstriction	Decreased breathing Cardiac arrhythmias Ventricular fibrillation Cardiac arrest Loss of consciousness Amnesic episodes Ischemic stroke	Death	

FEV_1, forced expiratory volume in 1 s.

seasonal infections such as influenza and other factors, but the largest contribution is from low temperatures. Figure 1 shows the fraction of deaths in the United Kingdom that is attributable to monthly variation, before and after adjustment for influenza and low temperature (Wilkinson et al. 2004).

Analyses of seasonal distributions of health events usually compare event rates in two divisions of the year, most commonly winter versus nonwinter or winter versus summer. The difference between the selected seasons is expressed as an index, where a value of 1 indicates no difference between seasons; a value greater than 1, a winter excess; and a value less than 1, a summer/nonwinter excess. The most common metric used is Curwen's Excess Winter Mortality Index, which is calculated as the average deaths per day in the four coldest months (Dec., Jan., Feb., Mar. for the northern hemisphere and Jun., Jul., Aug., Sep. for the southern hemisphere) minus the average deaths per day over the warmer months divided by the average deaths per day over the warmer months. The formula for the northern hemisphere is as follows:

$$\frac{\frac{\sum_{\text{deaths}}[\text{Dec., Jan., Feb., Mar.}]}{121} - \frac{\sum_{\text{deaths}}[\text{Aug., Sep., Oct., Nov., Apr., May, Jun., Jul.,}]}{244}}{\frac{\sum_{\text{deaths}}[\text{Aug., Sep., Oct., Nov., Apr., May, Jun., Jul.,}]}{245}}$$

Alternatively, the annual distribution of deaths may be modeled as a sinusoidal curve, with the differences in deaths between one season and another measured as, for example, the difference between the top and the bottom of the curve, or alternatively the difference between the middle and the top of the curve.

Seasonal indices have the advantage of including health events due to longer term seasonal effects and can be used to calculate an estimated number of 'excess winter deaths,' which may provide a metric more meaningful to a lay audience.

Studies comparing excess winter mortality levels in different countries have found that New Zealand has a large excess and that within Europe, Portugal, Ireland, and the United Kingdom also carry a high burden (McKee 1989; Curwen et al. 1997). However, some of the low excesses observed in cold Scandinavian countries may be due to the use of arbitrary seasonal definitions (Wilson et al. 2001). Ascribing season based on calendar date is somewhat arbitrary, but assigning season in any other way complicates interannual comparisons.

Regardless of temperatures, winter mortality excesses may also be high in years experiencing major influenza epidemics. In addition, year to year changes in seasonal indices and absolute 'excess winter death' numbers are not ideal for measuring the future impact of climate, as increasing heat-related impacts in the comparison months may mean that a winter mortality index ostensibly reduces even if the true wintertime burden remains the same.

1.13.2.2.2 Studies Assessing Explicit Weather Factors

The acute relationship between health events and climate variables is most commonly estimated using regression analysis of time-series data measured over a period of a few years. These studies control for time trends and broad seasonal patterns, and also usually for time-varying confounders such as circulating infections and air pollution concentrations. The most commonly characterized relationship is that between the daily number of deaths and the daily ambient temperature measurements in any particular setting.

In many settings, mortality levels rise in a smooth, often linear, manner in relation to a fall in temperatures during winter months. This risk is sometimes referred to as the cold slope, and the steepness of the slope may vary across cities and countries depending on differing climatic, demographic, and socioeconomic profiles (Analitis et al. 2008).

One key consideration in the assessment of cold risk is that cold effects can be delayed by a few days or weeks following initial exposure. The effects of exposure may, therefore, be distributed across many subsequent days of mortality counts, thus leading to the need of studies of this type to simultaneously model exposure effects over multiple days. Such a distributed lag curve is shown for various outcomes in 15 European cities combined in Figure 2 (Analitis et al. 2008). It can be seen that the effect of cold on cardiovascular disease (CVD) deaths peaks a few days following exposure and then reduces to zero effect, whereas the respiratory deaths are much longer sustained. For each outcome, summing the effects of the individual lags provides a total effect of short-term exposure to low temperatures.

1.13.3 Risk Factors for Cold-Related Mortality and Morbidity

A person's susceptibility to cold weather is affected by both individual and contextual risk factors (Conlon et al. 2011).

1.13.3.1 Individual-Level Risk Factors

1.13.3.1.1 Age

While all people are susceptible to cold, some groups are more vulnerable than others. The most important risk factor for cold-induced illness and death is age, with the elderly and very young being at highest risk. While evidence for increased risk between middle and third age is occasionally mixed, studies of both mortality and morbidity universally find those aged over 60 years to be at greater risk than younger

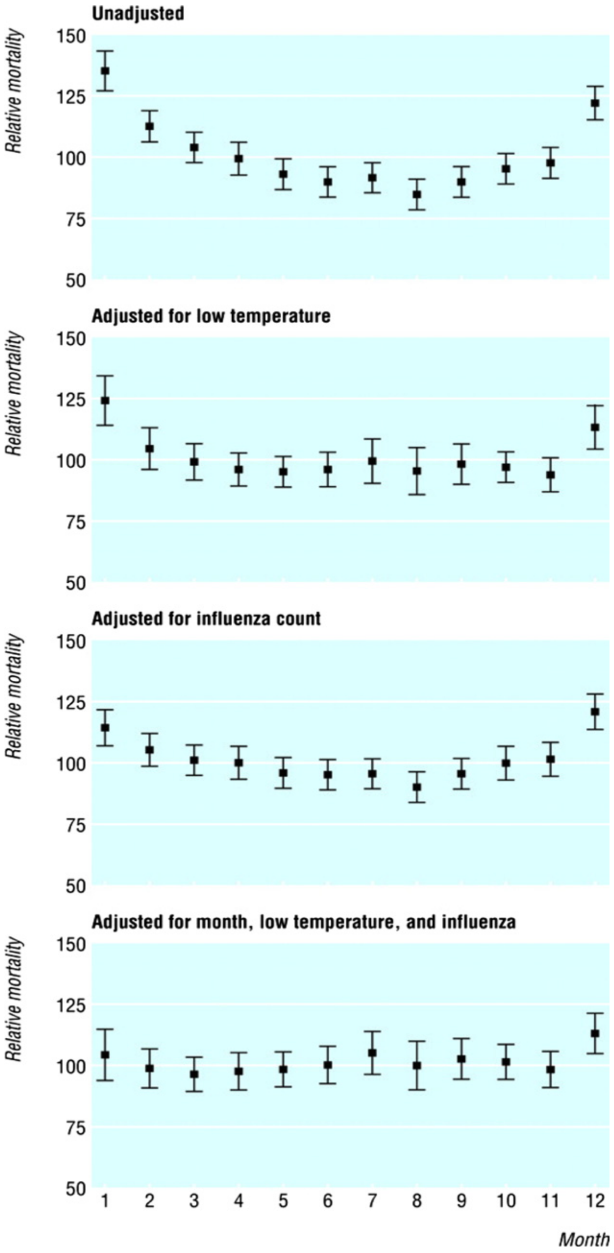

Figure 1 Fraction of deaths attributable to monthly variation. Reproduced from Wilkinson, P., S. Pattenden, B. Armstrong, A. Fletcher, R. S. Kovats, P. Mangtani et al., 2004: Vulnerability to winter mortality in elderly people in Britain: population based study. *BMJ*, **329** (7467), 647, Epub 2004/08/19.

adults and those under 5 years of age to be at greater risk than older children and young adults (Gemmell et al. 2000; Davie et al. 2007).

1.13.3.1.2 Preexisting Illness

Excess winter mortality and morbidity indices are higher for chronic respiratory and cardiovascular conditions, that is, chronic obstructive pulmonary disease (COPD), asthma, and chronic heart disease.

1.13.3.1.3 Sex

Women are generally found to be more susceptible to the effects of cold than men, at all ages (Keatinge 2002; Davie et al. 2007; Stewart et al. 2002). However, Curwen found no difference between over-45-year-old men and women between 1968 and 1985 in Britain. In the Czech Republic, mortality risk during cold spells was most pronounced in middle-aged men (Kysely et al. 2009).

1.13.3.1.4 Ethnicity

The presence or otherwise of differences in cold-impact by ethnicity is underinvestigated. While there are seasonal differences in vitamin D levels by ethnicity, studies in New Zealand have found no difference in excess winter mortality between Europeans and Maori or Pacific people in New Zealand (Telfar Barnard 2010; Davie et al. 2007) but excess hospitalizations were higher in winter for both groups (Telfar Barnard 2010). However, in the United Kingdom, Rudge and Gilchrist (2007) found that census enumeration districts with a higher percentage of white pensioners had higher winter counts of respiratory hospitalizations. An early South African study found differences in seasonal mortality distribution between 1968 and 1971 by ethnicity, but these differences were accounted for by higher rates of summer infant mortality due to gastroenteritis among nonwhite groups (Wyndham and Fellingham 1978). Among adults in seven US cities, cold effects were reported to be higher in blacks compared to whites (O'Neill et al. 2003).

1.13.3.2 Contextual Risk Factors

1.13.3.2.1 Socioeconomic Status

There is still debate over the degree to which socioeconomic status exacerbates or increases risks of cold exposure. Hales et al. (2010) found that those in the lowest income tertile in New Zealand had a 13% (95% confidence interval (CI) 8–19%) higher risk of winter death than those in the highest tertile. The strongest associations were seen for infectious diseases. Cold-related mortality risk in Sao Paulo, Brazil, was not found to be modified by area-level markers of socioeconomic position (Gouveia et al. 2003).

1.13.3.2.2 Rurality

The evidence for differences in effects of cold by rurality is varied or inconclusive. In the United Kingdom, excess winter mortality has not been found to vary by population density (Lawlor et al. 2002), although living in a rural area may increase the effect of socioeconomic deprivation (Hajat et al. 2007). On the contrary, two New Zealand studies have found urban dwellers to be at significantly increased risk of excess winter health events (Telfar Barnard 2010; Hales et al. 2010). A spatial analysis of temperature extremes in Taiwan found greater vulnerability in rural areas compared to metropolitan regions (Wu et al. 2011).

1.13.3.2.3 Housing

The evidence implicating poor housing in cold-related mortality or morbidity is mixed (Barnard et al. 2008). Ecological evidence tends to show no effect; individual-level

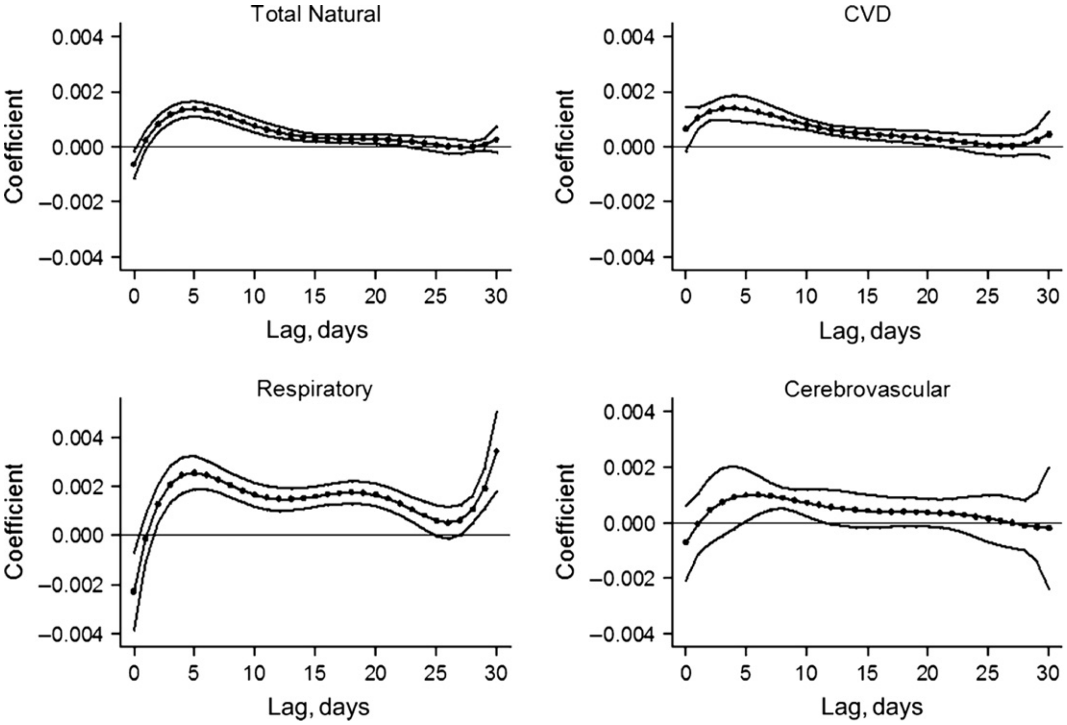

Figure 2 Distributed lag curves (and 95% confidence intervals) up to 30 days of the effect of a 1 °C lower apparent temperature on daily number of deaths, all ages, during the cold season (Oct.–Mar.), 1990–2000. Reproduced from Analitis, A., K. Katsouyanni, A. Biggeri, M. Baccini, B. Forsberg, L. Bisanti, et al., 2008: Effects of cold weather on mortality: results from 15 European cities within the PHEWE project. *Am. J. Epidemiol.*, **168** (12), 1397–408, Epub 2008/10/28.

studies show some effect, with indoor temperature being more important than other housing indicators such as dwelling age or presence of central heating. Tenure may also make a difference: New Zealanders living in rented accommodation were at greater risk of winter death than home owners (odds ratio 1.05 (95% CI 1.01–1.10)) (Hales et al. 2010).

1.13.3.2.4 Household Crowding

We were unable to find any studies that measured the effect of household crowding on cold-related health events, but as household crowding is generally found to contribute to increased risk of respiratory infection (Cardoso et al. 2004) and respiratory infections make up a large percentage of winter health events, household crowding may contribute to the winter health burden.

1.13.4 Adaptations

The fact that wintertime health impacts are not necessarily largest in the coldest countries indicates that adverse cold-related health events are largely avoidable and that adaptations to cold weather will play a key role in determining current and future cold-related health burdens.

At an individual level, human adaptation to cold weather can not only be physiological but also due to changes in behavioral responses. Some short-term physiological adaptation to cold can be achieved within 2 weeks of exposure (Rintamaki 2007). Thermoregulatory responses to cold are either insulative (e.g., circulatory adjustments) or metabolic (shivering) (Makinen 2010). Most experimental evidence on physiologic responses to cold exposure is based on studies conducted on healthy individuals in sports and military settings. However, a person's ability to thermoregulate adequately is affected by factors such as fitness, body composition, underlying health status, and age. Elderly people are most vulnerable to cold exposure, in part due to a reduced ability to retain body heat. Children also can lose heat quickly because of a higher surface area ratio compared to adults; however, this may be partially offset by a higher metabolic rate (McCullough et al. 2009).

Differences in behavior are likely to explain much of the variation in cold risk observed between countries. In general, cold weather-related health burdens tend to be largest in countries that experience mild winters, whereas countries that are used to harsh winters and are well adapted to them have lower risk. This indicates that relative temperature levels are more important than absolute values in determining health risks. A study conducted in one of the world's coldest cities – Yakutsk, in Eastern Siberia – found that all-cause mortality and mortality specifically due to ischemic heart disease and stroke did not rise as outdoor temperatures fell to −48.2 °C (Donaldson et al. 1998). Those surveyed in this study reported wearing very warm clothing during the winter and staying indoors in warm housing when the weather became extremely cold. Another study comparing European regions observed that the mortality risk was greatest in regions with warm winters, in populations with cooler homes, among people who did not regularly wear hats, gloves, and anoraks and were less active outdoors (Cold exposure and winter 1997).

One of the key contextual ways that societies can adapt to cold weather is through the built environment, especially housing. Internal temperatures of a person's home contribute greatly to overall exposure to cold. In many countries, people spend more than 90% of their time indoors, mostly in their own homes. (Chapman et al. 2009). The insulation of homes in low-income communities in New Zealand led to improvements in various health outcomes among occupants, although these were all based on self-reported measures (Howden-Chapman et al. 2007). In a follow-up to this study, no improvements were found in clinical measures of lung function among asthmatic children in the insulated homes, although improvements were observed based on self-reported measures (Howden-Chapman et al. 2008). A cost–benefit analysis of this insulation program concluded that the total monetary values in health gains and in energy and greenhouse gas emissions savings in these homes was 1.5–2 times greater than the cost of retrofitting the insulation (Chapman et al. 2009). In general, the link between housing quality and wintertime health is still inconclusive (Barnard et al. 2008).

One specific factor that has been linked to cold risk and housing is a lack of affordable warmth, also known as fuel poverty. In the United Kingdom, households that require 10% or more of their income to achieve adequate warmth in the home are classified as being in fuel poverty (Sefton and Chesshire 2005). In England, 12% of households were fuel poor in 2006 and the rate was double in Scotland (Liddell and Morris 2010). **Figure 3** shows the percentage of fuel-poor households in England, by type of occupant (DoEaCC 2010). About half of the people in fuel poverty in England are over 60 years of age.

Interviews of occupants in households who had benefited from the Warm Front scheme (a government initiative aimed at alleviating fuel poverty in England by improving home heating) found that recipients reported improved perceptions of physical health and comfort, especially of mental health and emotional well-being (Gilbertson et al. 2006). There were also reports of improved family relations and greater use of kitchens and better nutrition. However, heating bills were not substantially lower. A recent comprehensive review of fuel poverty and human health concluded that there is little evidence to date of physical health improvements in adults receiving fuel poverty interventions, although their *perceptions* of well-being were improved and physical health gains among children were more evident (Liddell and Morris 2010).

Although most evidence to date on cold impacts comes from high-income settings, reducing global burdens will require greater identification of vulnerable groups in other settings and feasible options for interventions, such as in rural Bangladesh (Hashizume et al. 2009). The introduction of energy-efficient measures also has the potential for other health impacts, both positive and negative – for example, changes in home ventilation could have adverse health impacts as a result of increased exposure to indoor pollutants (Wilkinson et al. 2009). In low-income countries, the current use of biofuels for domestic cooking and heating can lead to exceptionally high levels of exposure to some pollutants.

1.13.5 Implications of Public Health Policy

Some countries now have policies to minimize cold-related health impacts on public health. In many cases, these relate to strategies to improve housing conditions for vulnerable members of society. The UK Fuel Poverty Strategy seeks to eradicate fuel poverty by 2018, first by targeting three vulnerable groups: people aged over 60 years, those with disabilities or long-term illness, and families with children; in the second phase, nonvulnerable groups will be prioritized (BERR 2001). Such strategies may also require better measurement of what constitutes fuel poverty (Hills 2011).

In some countries, governments are now introducing integrated cold weather response plans which besides planning long-term intervention strategies also trigger acute intervention measures. Since the winter of 2011, England has had in operation a cold weather plan run by the Department of Health (DH 2011). The plan provides advice for individuals, communities, and agencies on how to prepare for and respond to severe cold weather and initiates acute actions by health and social care professionals and other community organizations to strengthen the protection and support of vulnerable individuals when cold weather is forecast.

The advice that is given to vulnerable individuals in such plans should consider the potentially sensitive nature of categorizing a person as being high risk. A recent qualitative study concluded that practices and devices strongly recommended to older people and past generations tend to be heavily stigmatized, leading to resistance from individuals to follow age-related advice (Day and Hitchings 2011).

Although most policy actions relate to keeping houses warmer during winter, exposure to cold outside of the home is also important (Keatinge and Donaldson 2004). The DH cold weather plan provides guidance to individuals not only on keeping warm at home but also on activities and clothing when outdoors. It has been suggested that measures such as windproofing bus shelters and better heating of waiting rooms could reduce the cold burden further (Keatinge and Donaldson 2004).

Also, in the United Kingdom, the Government weather service, the Met Office, has in place a health forecasting system, whereby weekly risk predictions for emergency hospital admissions for COPD are provided to participating hospitals to aid clinical management. The risks are based on models combining weather forecasts with information on infectious disease activity and other seasonal parameters.

Globally, the World Health Organization supports national authorities in developing and revising cold weather plans in order to promote public health preparedness during winter and cold weather (World Health Organization 2012). They stress that preparedness plans should be implemented in coordination with other sectors – such as housing, energy, transport, and education.

1.13.6 Conclusions

Although concerns about global warming have recently focused on the dangers of exposure to hot weather, cold-related exposure remains a substantial public health problem in many parts of the world. This may be exacerbated by recent global increases in fuel prices, leading to a greater inability among people to warm their homes adequately during cold weather. Intervention measures designed to minimize cold exposure and reduce fuel poverty will play a key role in determining current and future health burdens due to cold weather.

Glossary

Adaptation Adaptation to climate change is the adjustment of a system to moderate the impacts of climate change to take advantages of new opportunities or to cope with the consequences (Adger et al. 2003).

Adaptive capacity The ability of a system to adjust to climate change (including climate variability and extremes), to moderate potential damage, to take advantage of opportunities, or to cope with the consequences (IPCC 2007b). Adaptive capacity is shaped by available resources, institutions, and skills and knowledge among others.

Climate Usually defined as the average weather, or more rigorously as the statistical description in terms of the mean and variability of weather (surface variables such as temperature, precipitation, and wind), over a period ranging from months to thousands or millions of years. The classical period is 30 years, as defined by the World Meteorological Organization (WMO) (IPCC 2007b). An alternative definition is the system consisting of the atmosphere, hydrosphere, lithosphere, and biosphere determining the Earth's climate as the result of mutual interactions and responses to external influences (forcing). Physical, chemical, and biological processes are involved in interactions among the components of the climate system (NRC 2005), AMS. Dominant natural forcings are solar and volcanic action.

Climate change according to the UNFCC A change of climate that is attributed directly or indirectly to human activity that alters the composition of the global atmosphere and that in addition to natural climate variability is observed over comparable time periods (UNFCCC 1994). Such factors include increased greenhouse gas (GHG) concentrations associated with fossil fuel burning, sulfate aerosols produced as an industrial by-product, ozone (stratospheric and tropospheric), and human-induced changes in land surface properties.

Coping capacity The manner in which people, organizations, and societies use existing resources to achieve various beneficial ends during and immediately after unusual, abnormal, and adverse conditions of a disaster event or process. Strengthening of coping capacities can build resilience to withstand the effects of future natural and other hazards.

Coping strategies Short-term actions to ward off immediate risk, rather than to adjust to continuous or permanent threats or changes. Coping strategies are 'first-resort' responses, and can become part of the 'repertoire' of behavior to also be used to respond to recurrent problems. Note, as directed at immediacy, they are not necessarily well targeted as a long-term strategy, so when used as a response to stress, it is possible that vulnerability may increase in the long term (Schipper et al. 2008).

Ecosystem The sum of the living organisms in an area and nonliving chemical and physical factors with which those organisms interact. *Healthy ecosystems* provide a variety of services to humans, most obviously providing food, water, and shelter, in addition to life-supporting functions by purifying air and water, nutrient cycling, and detoxification and decomposition of wastes.

Hazard A potentially damaging physical event, phenomenon, or human activity that may cause the loss of life, injury, property damage, social and economic disruption, or environmental degradation (ISDR Scientific and Technical Committee 2009).

Health determinants Certain upstream or distant factors have great potential to impact on public health, even though these exposures are far apart in time or space from the witnessed ill-effects relates. Determinants of health include policies, for example, those that drive current levels of population growth, consumption, and waste issues and the uses of technology.

Maladaptation An action or process that increases vulnerability to climate change-related hazards. Maladaptive actions and processes often include planned development policies and measures that deliver short-term gains but lead to exacerbated vulnerability in the medium to long term (UNDP 2011).

Micronutrients Essential dietary elements (vitamins and minerals) that are needed only in very small quantities. They include copper, zinc, selenium, iodine, magnesium, iron, cobalt, and chromium and vitamin A. Micronutrient deficiency is a lack of one or more essential vitamins or minerals such as vitamin A, iron, or zinc.

Resilience The ability of a social–ecological system to absorb disturbances without losing its fundamental structure and function (combination of definitions).

Risk The probability of harmful consequences, or expected losses (deaths, injuries, disease, property, disrupted livelihoods or economic activity, environmental damage) resulting from interactions between natural or human-induced hazards and vulnerable conditions. Conventionally, risk is expressed by the notation Risk = Hazards × Vulnerability.

Social determinants of health The social determinants of health are the conditions in which people are born, grow, live, work, and age, including the health system. These circumstances are shaped by the distribution of money, power, and resources at global, national, and local levels, which are themselves influenced by policy choices. The social determinants of health are mostly responsible for health inequities – the unfair and avoidable differences in health status seen within and between countries.

Stunting When children are too short for their age – as a result of chronic malnutrition.

Undernutrition Exists in several forms: stunting, wasting, or micronutrient deficiency (see definitions in this section) Causes include inadequate diet and infection, and it is usually associated with a lack of access to sufficient quantities of nutritious food, clean water, sanitation, or health care.

Vulnerability In the context of climate change, vulnerability is the degree to which a system is susceptible to, and unable to cope with, perturbations or stress associated with climate change, including climate variability and extremes. Vulnerability to climate change is a function of (1) the character, magnitude, and rate of climate stress, and the variation to which a system is exposed; (2) its sensitivity to these factors; and (3) its capacity to recover from, or fundamentally adapt to, these influences.

Wasting When children are too light for their height – as a result of acute malnutrition.

Weather Unlike *climate*, which is long-term phenomenon, weather is a short-term (minutes to weeks) phenomenon, describing atmosphere, ocean, and land conditions hourly or daily. Weather is not constant. It is dynamic and always changing. Weather is the day-to-day state of the atmosphere, measured and recorded in terms of temperature, humidity, precipitation, cloudiness, visibility and wind, and their short-term variation (WMO and a combination of definitions).

1.14.1 Introduction

> “Climate change is among the most serious challenges facing Pacific Island countries and territories, threatening every aspect of their environment, social and economic development, and political and human security. The nature of these small countries – often sparsely populated atolls in a vast ocean – makes them highly vulnerable to the projected effects of climate change. For some of the 22 member countries and territories of the Pacific Community, it is a question of survival, and for all of them, a time for action.”
>
> Commonwealth Health Ministers’ Update 2009 (Rodgers et al. 2009).

The relationship between climate change and human health is enmeshed in a complex web of interlinked and overlapping pathways. Direct impacts of climate on human health can be readily seen, most notably in extreme events. These are immediate and often dramatic, and these events feature widely on international news media, in the form of broad-scale disasters wreaking havoc on hapless populations. Indirect effects arising from these extremes, increasing climate variability, or indeed slow shifts in climate patterns are often more insidious in their action and more entrenched as they interfere with basic necessities of life that are fundamental to human health and well-being. From the community’s standpoint, effects of climate change can arise through different pathways, such as via interruptions to ecosystems or fragmentation of sociocultural and economic infrastructure. Effects become insidious when they act in concert and create a multiplying effect that further reduces resilience to climate extremes and existing social challenges, thereby deepening vulnerability and entrenching long-term disadvantage.

Not all effects of perturbations in climate systems would be deleterious to human health and well-being. In certain circumstances, there would be some positives; however, the global net impact is predicted to be negative (Nicholls 2011) and not evenly distributed between regions, countries, or subpopulations within countries. ‘Communities,’ in this chapter, can be regional (e.g., Mediterranean, African), national (e.g., Sudanese, Tongans), or subgroups (e.g., farmers, children, or the socioeconomically disadvantaged).

One clear example of a climate change benefit exists for communities from cool countries, such as the United Kingdom, where warming is likely to result in a net reduction in temperature-related deaths. By the 2020s, 2050s, and 2080s, premature deaths are estimated to reduce by approximately 15%, 30%, and 45%, respectively. Owing to the current high numbers of annual cold deaths (estimated between 26 000 and 57 000 per year), this health gain outweighs the estimated 60% increase in heat-related morbidity in the near term (2020s), and approximates 200% increase in the medium term (2050s), based on the medium emissions scenario, central estimates. However, this benefit noticeably narrows by the 2080s (DEFRA UK 2012). This is not to suggest that the overall impact for the United Kingdom would be beneficial. The *UK Climate Change Risk Assessment 2012 Evidence Report* concludes that the combined effect of all the manifestations of climate change will bring a net deterioration. It is pertinent therefore for the public health effort to focus on the *health threats* arising from global warming and increasing climate variability and to assess what strategies are required to minimize health harm. This chapter will primarily address health threats among highly vulnerable communities and the mechanisms underpinning vulnerability to climate change.

Tracking the various vulnerability pathways highlights the special needs of vulnerable communities and is key to understanding both the complexity and the urgency of action required. When examining the problem from a multi-perspective approach, it becomes readily apparent that attacking complex problems with singular linear responses is unlikely to make significant inroads. In this chapter, vulnerability to climate change is examined through the lens of food insecurity and multigenerational disadvantage. Food insecurity has been predicted to emerge as a global climate change risk, striking first on already vulnerable communities. Small Island Developing States (SIDS) are considered especially vulnerable to the net effects of global warming and increasing climate variability. Pacific Island countries provide a useful case study to demonstrate the interaction of complexities involved and to illustrate the pervasiveness of flow-on vulnerability effects that can reduce resilience in future generations.

The states that comprise the Pacific Island Countries and Territories (PICTs) lying south of the Tropic of Cancer are traditionally aggregated into three major groups: Melanesia, Polynesia, and Micronesia – reflecting the diverse geography, culture, and ethnic backgrounds of the indigenous inhabitants of the islands. This chapter will refer to those 22 PICTs served by the Secretariat of the Pacific Community (SPC).

- Melanesia (*black islands*) include Papua New Guinea (PNG), New Caledonia, Torres Strait Islands, Vanuatu, Fiji, and the Solomon Islands, plus some Indonesian provinces.
- Micronesia (*small islands*) lie mostly north of the Equator and include the Federated States of Micronesia (FSM), Marshall Islands, the Marianas, Kiribati, Nauru, Guam, Wake Island, and Palau.
- Polynesia (*many islands*) cover the largest area and include Tonga, Samoa, Tuvalu, American Samoa, Samoa, Cook Islands, Pitcairn Islands, Tokelau, New Caledonia, Niue, French Polynesia, Wallis, and Fortuna.

Although many similarities are shared by these 22 PICTs, country geomorphology and sociogeopolitical features vary greatly. However, governments of these three Pacific Island regions agree that climate change poses a serious threat to all small island states and coastal populations (Secretariat of the Pacific Regional Environment Programme (SPREP) 2011; WHO Western Pacific Regional Office & SPC 2009). Our discussion does not consider Australia and New Zealand as small Pacific Islands.

The SPC receives financial support from France, Australia, New Zealand, and the United States to assist these PICTs achieve their development goals.

1.14.2 Climate Change: Determinants of Vulnerability

The World Meteorological Organization (WMO) defines a region's climate as the pattern of weather occurring over a 30-year period. As weather varies daily, climate is also variable. In human relevant time spans, a region's weather patterns will most commonly vary within a defined range, and this range oscillates seasonally yet within a broader envelope according to cycles driven by the influence of large systems such as the tropical multidecadal signal and the El Niño-Southern Oscillation (ENSO). ENSO is particularly significant in determining weather patterns across the Pacific Ocean. (The Earth's climate has also cycled through ice ages, and interglacial warm periods over longer frames of 100 000 years or so.) Stepwise shifts occasionally do occur, such as the one that occurred in the repeated dry periods at about 2000-year intervals in the Sahara during the Holocene (Mercuri et al. 2011), and there are more recent examples such as the recent halving of the rainfall in southwest western Australia (Bates et al. 2008; Timbal et al. 2006). Both are thought to be in response to anthropogenic landuse activities. Most weather that we observe occurs within the boundaries of these short-term cycles, which serve to define a region's climate, and a shift outside the boundaries indicates that the climate has changed. The IPCC defines 'climate change' as a change in the state of the climate that can be identified (e.g., by using statistical tests) by changes in the mean and/or the variability of its properties and that persists for an extended period, typically decades or longer. The persistence and time frame are critical to detect real shifts over and above the routine variation in weather.

Extreme weather events are defined as the occurrence of a value of a weather or a climate variable that falls above (or below) a threshold value near the upper (or lower) end of the range of observed values of the variable. Weather extremes fall at either tail of the distribution curve, and new weather records are set when extremes occur beyond the past recorded level. Historically, records are broken relatively infrequently and usually, only by small margins, which means the new record lies just a small margin *outside* the previous known extreme. Globally, the rate of weather records being broken has increased, and records are being broken by unusually large margins (Coumou and Rahmstorf 2012; Nicholls 2009). This increase in extremes is consistent with an increasing variability, as predicted by climate models, and suggests that a change in climate is underway.

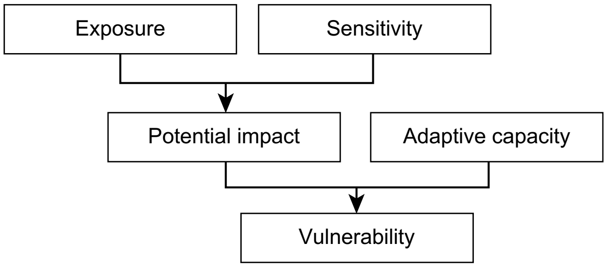

Figure 1 Components of vulnerability. Adapted from Schroeter D and the ATEAM Consortium, 2004: Global Change Vulnerability – Assessing the European Human-environment System: Potsdam Institute for Climate Impact Research.

Vulnerability to climate change is defined by the IPCC as "the degree to which a community, individual, or the environment is susceptible to and unable to cope with adverse effects of climate change" (UNFCCC 2011). In the context of human health, there are four determinants of vulnerability that need to be considered: exposure, sensitivity, potential impact, and adaptive capacity. **Figure 1** is often used to depict how these various forces interlink to construct a situation of vulnerability.

All countries are *exposed* to climate perturbations arising from their climate extremes, but how they are exposed to increasing climate variability as part of a changing climate will differ spatially and in type and intensity. Exposure intensity is a measure of the degree of climate extremes occurring, such as the temperatures reached and the duration of heat waves, the wind speeds of typhoons, the amount of rainfall over a given period, the length of drought, or the depth of floods. Alternatively, a significant deviation from the climate norm can constitute high-level exposure without the occurrence of extreme events, for example, a climate shift to a new state where the local ecosystems can no longer thrive. Plants evolve within a climate and require established patterns, such as cold nights or frosts, to complete their annual cycle. Total annual rainfall may remain relatively constant, but may shift between seasons, away from germination or peak growing times, and fall instead when harvest is due, or may shift toward fewer but heavier precipitation events. In this scenario, less rain seeps into the ground. Soil moisture is depleted to create drought-like conditions, which compromises agricultural yield, livelihoods, and food supply (IPCC 2008).

Sensitivity, as the name implies, relates to the susceptibility of the system to the exposure. Plants sensitive to temperatures include those that need frosts to generate bud burst and those that suffer leaf burn in frosts. Low-lying atolls, such as those in the Pacific, are highly sensitive to storm sea surges, as they have little protection from inundation that can introduce salty water in the water lens or salinate the soil. In relation to health, humans can tolerate a very narrow range in their core temperature (Hanna et al. 2011); we are sensitive to exposure to extreme heat and cold.

Combining the effects of exposure and sensitivity produces the *potential impact*. Using the above examples, atoll nations situated in the tropics are therefore exposed to strong tropical storms. Atolls are low lying and are highly sensitive to ecosystem interruption and infrastructure damage by big waves. Warm oceans generate strong cyclones or typhoons that in turn generate high seas and storm surges, and therefore, the potential impact for low-lying areas such as atolls from continued warming of the oceans is extremely high. Although episodes of low cyclonic activity continue to occur, notably during La Niña cycles, they are predicted to increase in intensity with climate change (Australian Bureau of Meteorology and CSIRO 2011b).

Countries with high *adaptive capacity* are better able to withstand climate extremes. Coastal mangroves help dissipate storm sea surges and minimize damage; hence a natural abundance or protection of native mangroves offers natural protection for low-lying lands. In the absence of mangroves, erection of sea walls can assist in deflecting storm surges to protect coastal areas; however, these are costly and require financial investment. Countries with sufficient elevated land can consider relocating low-lying populations to higher ground. These examples illustrate how adaptive capacity can take the form of *having options* to avoid or militate against the risk and *taking up options* such as building sea walls to protect against storm surges.

Technology and infrastructure can significantly contribute to the array of available options to help minimize harm. For example, weather warning systems (Paul 2009) and health care systems that effectively reach vulnerable community members may offer protection. Having technical knowledge and financial resources to identify and implement options provides a degree of protection from the potential impact of climate change. However, nontechnical solutions are also important. Strong social networks and access to traditional elders' knowledge provide support to communities in stress and boost resilience and have been the historical cornerstone of survival against previous climatic challenges. Also critical to success is the willingness to engage in adaptation at the national, community, and personal levels, as many barriers to adaptation are social in origin (Jones 2010).

Adaptive capacity is, however, constrained in countries that lack access to sufficient technical, human, and financial resources or that have limited (or lost) local knowledge, limited social services, or limited suitable infrastructure and flexible systems. Populations with only few options available to them have limited capacity to successfully avoid harm. Furthermore, their postdisaster recovery can be slow. Climate-induced natural disasters have been shown to delay progress toward achieving Millennium Development Goals (MDGs) by a decade or more (UNESCAP 2011).

To bring all these together, *vulnerability* is first a function of the degree of population or individual's exposure to significant changes in climatic variables and the sensitivity to these climatic variables, which combined, generate the potential impact. Adaptive capacity then moderates that potential impact to determine the actual residual vulnerability.

It is important to recognize that not all members within a particular community will be equally vulnerable. Societal inequality influences both the extent of the health impact through the exposure and/or sensitivity pathway and the capacity of an individual or community to access adaptive options. An example of this differential at work occurred in New Orleans when the wealthy, informed, and mobile residents were better able to evacuate before Hurricane Katrina struck. People without such advantages were, through their lack of access to options, forced to remain and endure the consequences. Vulnerable subgroups are at increasing risk of having their vulnerability further exacerbated, as globally the gap between rich and poor is widening. Despite a surge in the size of the 'global middle class' between 1990 and 2005, the average country level income inequality increased around 20% (United Nations Secretary-General's High-level Panel on Global Sustainability 2012).

The relationship between exposure and incidence of harm is nonlinear. According to available global statistics, least developed countries (LDCs) represent 11% of the population exposed to natural hazards but account for 53% of casualties. This contrasts the situation for populations in the most developed countries, which represent 15% of human exposure to hazards but account only for 1.8% of all victims (Peduzzi et al. 2009). Complex factors therefore intervene in the translation of exposure risks and ultimate outcomes. The relationship between natural disasters and vulnerable populations has been described as a *double disadvantage*. The reason is that disasters present a feedback loop. First, they impact more heavily on disadvantaged populations, and the disproportionate damage incurred then further disadvantages these groups. Countries that are currently disadvantaged by retarded progress toward achieving MDGs commonly face additional burdens such as physical isolation; shortages in natural, human, and financial resources; and preexisting climate challenges. Collectively, these serve as barriers to countries reaching their MDGs. This situation exists in many Pacific Island countries.

Real concerns exist for escalation of vulnerability, as stalled international agreements for mitigation action have failed to make significant inroads in abating global greenhouse gas (GHG) emissions. This is despite the 100-year knowledge that emission of GHGs through the burning of fossil fuels increases atmospheric GHG concentrations and results in warming (Earth Observatory 2010). Current GHG levels will continue the process of warming for many centuries, even if emissions completely cease in 2012 (Gillett et al. 2011). Other human activities are exacerbating this trend.

A guardrail limit of 2 °C average global warming is the proposed international policy target, despite being acknowledged as 'not safe,' and would still accord future climate disasters and associated human misery. The 2009 Copenhagen Climate meetings agreed that there was "virtually no chance of limiting warming to 2 °C above preindustrial temperatures" (New et al. 2011). Extreme events are, by definition, rare. Heat extremes at three standard deviations (3σ) from the norm usually cover less than 1% of the globe in any given year. Over the past decade, these 'extreme extremes' have covered an unprecedented 10% of the globe, leading climate scientist, James Hansen (Goddard Institute for Space Studies) to predict that these extremes will become the new norm and that the 'new extreme' will be 5σ (Hansen et al. 2012).

A 66% probability now exists that such a high-emission nonmitigation future will yield warming outcomes in the range of 4.0–6.1 °C by 2100 (Rogelj et al. 2012). There are no projections as to whether such a world could support any semblance of life as we currently know it when weather extremes across the globe are increasingly falling outside the boundaries of customary extreme levels, with the relatively moderate average global warming reported by the IPCC in 2007 being 0.74 °C (IPCC, 2007c). Subsequent years since the publication of this report have been still hotter. Munich (2011) have been analyzing weather-related catastrophes for over 35 years and report that these catastrophes have almost tripled since 1980, flood loss events have gone up by a factor of more than three, and the number of windstorm natural catastrophes has more than doubled.

1.14.3 Pacific Island Exposure to Climate Change

Although a convincing body of evidence now exists demonstrating that the planet is warming, large uncertainties remain about the exact nature and timescales of future changes at the local level (IPCC 2012). Uncertainty about human responses to mitigation significantly contributes to this uncertainty. An indication of what can be expected from climate change, at the local scale, lies in the natural variation in existing weather patterns, as in addition to the warming trend, greater climate variability will amplify the extremes of current weather patterns (Durack et al. 2012). In 2011, the Australian Bureau of Meteorology (BoM) and the Commonwealth Scientific and Industrial Research Organisation (CSIRO) released downscaled projections for the Pacific Islands to assist the region to prepare for and adapt to increasing climate variability (Australian Bureau of Meteorology and CSIRO 2011c). Owing to the large geographical area, considerable variation exists in the modeled projections for future climate throughout the Pacific. Broadly, countries that experience extreme heat and droughts are likely to see more intense heat extremes and longer and more protracted droughts (Australian Bureau of Meteorology and CSIRO 2011c). Similarly, countries exposed to monsoonal weather patterns are likely to experience greater future rainfall variation, with some delays and weakening of monsoons and some intensifying of the monsoonal systems (Australian Bureau of Meteorology and CSIRO 2011b; IPCC 2007b).

PICTs are situated in cyclone- (typhoon-) prone areas and are subject to the vagaries of the ENSO, which bring quasi-cyclical rainfall variation. The waters in the western tropical Pacific are the world's warmest, and this and other unique features give rise to tropical cyclones (TCs) that can produce storm surges and flooding (Australian Bureau of Meteorology and CSIRO 2011a). Global monitoring of cyclones has been restricted to a short observational period and a changing observational capability through time. Owing to this insufficient data record, some researchers argue that it remains difficult to isolate significant trends in cyclone behavior (frequency, intensity, rainfall, etc.) over the background variation (Knutson et al. 2010). However, Elsner et al. (2008) analyzed satellite-derived lifetime-maximum wind speeds of TCs grouped by year over the period 1981–2006. They concluded that satellite measurements offer conclusive evidence showing significant increasing trends in maximum wind speeds of the strongest TC globally. This finding is qualitatively consistent with the heat-engine theory of cyclone intensity, that, as seas warm, the ocean has more energy that can be converted to TC wind.

Indeed, many PICTs are already experiencing early indications of new weather regimes. In October 2011, Tuvalu was forced to declare a state of emergency and sought urgent external assistance to facilitate water desalination. After a 6-month drought, drinking water supplies had run out and animals began dying after drinking the residual contaminated ground water. In the same month, exceptional monsoonal rains north of Bangkok generated the regions' worst flooding in decades. Shifts in the global frequencies and intensities of extreme heat waves, wildfires, droughts, and storm systems are already being observed across the globe. Coastal erosion and storm surge inundation are also becoming more common (IPCC 2012).

The January 2009 floods in Fiji were reported as the worst in the history of the country since the 1931 floods (Lal et al. 2009). Many parts of the country were affected by a number of consecutive flood events that spread over several days. The recent global assessment report on natural disasters of the United Nations shows that the number of natural disasters, the number of economic losses, and the number of people affected are increasing at a rapid rate and faster than risk reduction can be achieved (UNISDR 2009). Since the start of the new millennium, 2500 disasters have affected billions of people around the world. These crises destroy infrastructure, displace entire populations, and threaten ecosystems and people who rely on them to survive. Kofi Annan (Secretary General of the United Nations) reported in 1999 that 90% of the disaster victims worldwide live in developing countries, where poverty and population pressures force people to live in harm's way (Asian Development Bank 2011). He argued that the vulnerability of those living in risk-prone areas is perhaps the single most important cause of the observed inequitable distribution of disaster casualties and damage. Reducing the risk of disasters and conflicts, mitigating their impacts when they occur, and building resilient societies and economies are therefore at the top of the international agenda (UNEP 2010).

1.14.4 Pacific Island Sensitivity to Climate Change

The heightened sensitivity of the PICTs relates to particular characteristics, primarily their geomorphology, their relatively small size and isolation, and their level of economic development.

This region is characterized by volcanic archipelagos composed of low-lying islands and atolls where climate-related sea level rise could further amplify other stresses caused by natural phenomena (such as vertical ground movements due to tectonics and volcanism as well as the occurrence of extreme events such as storm surges) or human activities (Becker et al. 2012). Between 1993 and 2001, sea level rise over the western Pacific Ocean approached 30 mm year^{-1} (Church et al. 2006).

Sea level rise presents as the most certain and potentially devastating climate change impact for PICTs (Rodgers et al. 2009). Thermal expansion is contributing to rapid Pacific sea level rise, and this risk is especially pronounced for Funafuti Island (Tuvalu), where the 'total' rate of rise is found to be about three times larger than the global mean sea level rise over 1950–2009 (Becker et al. 2012).

Most of the 22 PICTs are classified as SIDS, as the combined land area covers only 553 959 km^2, with PNG accounting for 83% of this land area (FAO 2008). Dispersed over an area covering a substantial part of the earth's surface, PICTs are adopting the name the *Blue Continent*. A significant issue therefore for these scattered populations is 'the tyranny of distance,' which is exacerbated by having small populations, small economies, with the associated limitations in infrastructure and human resources, and high costs of connectivity. The combined effect significantly limits their options to initiate potent adaptive strategies.

Contributing to PICTs' climate sensitivity is their tropical climate, which brings a high prevalence of various infectious diseases – including food-borne and water-borne infections and several mosquito-borne infections (especially malaria in PNG, Solomon Islands, and Vanuatu and dengue in PICTs generally) (Cooper et al. 2002; Harley et al. 2011). Furthermore, as temperatures rise and climate variability increases, sensitivity to extremes of heat will also increase (including for outdoors workers) – especially among communities with high incidence of underlying cardiovascular and metabolic disorders (e.g., diabetes type II) (Hannaet al. 2012).

Existing climate among Pacific Islands offers significant challenges. These and other limitations, such as isolation and small land mass, contribute to the preexisting situation of slow progress toward achieving MDGs and development goals. The preexisting vulnerability of this region contributes to their sensitivity to shocks, regardless of the origin.

1.14.5 Pacific Island Potential Impacts of Climate Change

The potential impacts of natural disasters on PICTs cannot be overstated. These extreme events disrupt water and food supplies; damage infrastructure, buildings, and homes; destroy livelihoods; and bring an array of health problems. In the 1990s, for example, the cost of extreme events in the Pacific Island region was estimated to have exceeded US$1 billion. Losses caused by Cyclones Ofa and Val, which hit Samoa in 1990/91, totaled US$440 million, which was greater than the country's average annual gross domestic product (GDP) in recent years. In Niue, the damage bill from Cyclone Heta is estimated at about NZ$37.7 million, which is approximately 25% of Niue's GDP. Such proportional damage far exceeds the likely impacts for develop countries.

The full effect on population health of Heta has not been calculated, but it is likely to be significant, as health services were interrupted and livelihoods were hampered. The impact of this single event on the food security was profound. Cyclone Heta transitioned Niue from a food exporting country into one dependent on imports for the next 2 years (Food Secure Pacific Working Group 2008). Without good governance, extreme efforts of the local communities, and substantial external assistance, such destruction can reverse progress toward achieving MDGs by a decade (UNESCAP 2011). Such indications suggest that as climate change progresses, extreme weather events will drive the demand for increased effort to avoid further exacerbation of global health and development inequities and a widening of the gap between rich and poor nations.

Governments of PICTs recognize the potential impact of climate change. It poses a serious threat to most small island states and coastal populations. The 39th Pacific Island Forum Leaders in their Niue Declaration, warned "… urgent social, economic and security threats caused by the adverse impacts of climate change and sea level rise to our territorial integrity and continued existence as viable dynamic communities"(Pacific Islands Forum Secretariat 2008).

For many PICTs, sea level rise is arguably the most certain and potentially devastating climate change impact (Rodgers et al. 2009). Low elevation causes storm surge inundation of islands and salination of precious arable land and water supplies. A feature of many islands is having low-lying central areas excavated for production of taro. These low-lying areas are already subject to inundation, which will increase as the sea rises and threaten local food and water supplies (Woodroffe 2008). With limited available space, internal relocation of populations or agriculture is not an available strategy for many small island states. This reduces habitation adaptive options, amplifies sensitivity to natural disasters, and heightens vulnerability to the projected increasing intensity and frequency of these weather events (Hanna et al. 2012). Sea level rise could eventually make several countries, particularly atoll nations, such as Tuvalu, Kiribati, Tokelau, and the Keeling Islands, uninhabitable.

Higher islands are not immune to impacts from sea level rise. Higher islands anticipate losing significant proportions of their high-value land due to sea level rise, and Fiji and Samoa could also face serious challenges since most settlements and infrastructure cluster around the coastal zones. Their hilly inland regions may experience severe ecological changes because of mass relocation of migrants from the coast. Existing underlying health problems and limited local capacity to adapt also contribute to vulnerability.

Many Pacific Islands have a hot humid climate, and warming associated with increased climate variability would accentuate heat-exposure health risks. The potential impact of death from heat stoke is high when heat-sensitive humans, such as the very young, the aged, those with preexisting cardiac conditions, and those who need to continue working, are exposed to extreme heat events (Hanna et al. 2011). Humans begin to feel unwell when their core temperatures exceed 38 °C (~100 °F), and high humidity reduces the efficiency of physiological cooling mechanism of sweating.

Owing to the natural variability of climate, it has been difficult to attribute with certainty any specific extreme event, such as heat wave, to climate change. Authors examining single events continue to argue that specific heat waves could occur through natural climate variability alone (Dole et al. 2011). Indeed they could, and have done in the past. Chase et al. (2006) examined the 2003 European heat wave against data dating back to 1979 and analyzed the trends for extreme events – up to two standard deviations . Although concluding that the 2003 event exceeded three standard deviations (and was therefore *very extreme*), they argued that natural variability in the form of ENSO and volcanism was of much greater importance than any general warming trend in causing extreme regional temperature anomalies.

A widely adopted approach is to examine long-term trends that show a warming trend above the noise of natural variability (Nicholls 2009; UK Met Office Hadley Center 2008; Wu et al. 2012). Others examine the global pattern of record-breaking events. Globally, extreme heat events have been occurring with greater frequency, bringing temperatures and durations not previously experienced in recorded history (Hansen et al. 2012). Four of the world's leading climate research centers agree that the 10 hottest years on record have all occurred since 1998 (JMA – Tokyo climate Center 2011; NASA Goddard Institute for Space Studies 2010; NOAA National Climatic Data Center (U.S.) 2011; UK Met Office 2011).

In PICTs where temperatures and humidity are already high, which makes physical effort uncomfortable, the potential impact of further increases in temperature and humidity would create additional challenges for populations resident in these regions. Productivity can be threatened, and a healthy level of exercise is difficult to achieve against the risk of heat stress (Hanna 2010).

1.14.6 Pacific Island Adaptive Capacity

The pathway linking climate and human health is complex and multifactorial. Health effects arising from changes to local climate involving both extreme weather events and gradual shifts away from normal weather patterns are likely to be similarly complex. Contributing to the nature and intensity of associated health outcomes are the impacts exerted by changed weather patterns on local landscapes and ecosystem services, termed primary and secondary impacts (Butler 2010), and the degree of resilience or preparedness of the county's infrastructure to withstand these interruptions. All these factors influence a nation's capacity to offer population health protection and ultimately determine sequential health impacts.

The capacity of a country to withstand and cope with the added challenges of climate change is the ultimate determinant of vulnerability, and this is not a linear relationship. Relatively minor weather events can create major disruptions to health and development in developing countries that are already struggling to provide conditions for good health. In contrast, more major climatic events have been relatively well tolerated in countries with good underlying health status and highly specialized response and recovery systems. The differential can be seen by assessing the pre- and post-disaster living conditions. Wealthy countries can rebound quicker, whereas for poorer countries, depletion of internal resources commonly requires development aid and loans to rebuild major infrastructure and local livelihoods (Wisner et al. 2005). Recovery bills can channel the much needed resources from health-generating services, such as health and education. This impairment of earning and productive capacity of future generations is how disasters can generate a persisting influence, and notch by notch, lower community well-being. Repeated events eventually erode living standards.

Natural geophysical characteristics and high levels of economic and development contribute to adaptive capacity. Absence of these places limitations on a community's resilience to withstand challenges of the potential impacts of climate change.

The PICTs are classified as poor, falling in the low- and lower middle-income categories. The population of the region (10 million) has been predominantly rural, although urbanization is rapid and more than 50% of the population now resides in urban areas in a few countries (Pacific Institute of Public Policy 2011). Total population numbers are very small in several PICTs; for example, current estimates for Niue range from 1400 (Department of Foreign Affairs and Trade 2011) to 1000 (Pacific Institute of Public Policy 2011), and after peaking at 250 in the 1930s, the population in the Pitcairn Islands diminished to 63 people by 2009. In contrast, 6.7 million people live in PNG (World Health Organization Western Pacific Region 2011). Despite low total population numbers, some urban areas in the Pacific such as Tarawa in Kiribati and Majuro in Marshall Islands have extremely high population densities of up to 7000 people per square kilometer (Pacific Islands Forum Secretariat 2012). Significant Pacific Island populations now live abroad, primarily in Australia, New Zealand, and the United States. While this diaspora helps the local economy through remittances home, it undermines the skilled workforce capability and capacity in critical areas such as health (Russell 2011).

The adaptive capacity of PICTs to climate change is extremely limited because of their small populations and economies, isolation, limited human and ecological resources, and dependence on international trade and in some cases foreign aid (Secretariat of the United Nations Framework Convention on Climate Change 2007).

1.14.7 Pacific Island Vulnerability to Climate Change

It can be seen then that the ultimate level of vulnerability is derived from a combination of these determinants. The main factors accounting for risk are intensity of the hazard (exposure), sensitivity of the local environment, culture, and population, which together generate potential impact, and the levels of poverty and governance determine the adaptive capacity. The increasing intensity of TCs is associated with increasing mortality, direct human exposure, and the number of coastal population living in low-lying areas being especially vulnerable to the high winds in category V and above. The protective power of adaptive capacity ought not be underestimated. A trend analysis of mortality risk based on the observed TC database conducted by Peduzzi et al. (2012) demonstrated that vulnerability parameters carry more weight in less-intense TC and, conversely, that the role of population exposure in mortality risk grows with the intensity of the TC. Their analysis revealed that poverty levels (low GDP per capita) accounted for 91% of the mortality loss for category I TC, yet this decreased to 31.1% for category V. At lower cyclone intensities therefore, only the poorest suffer heavy losses, whereas in very intense TC, the impact is more evenly felt, at least in the immediate term. Coastal population living in low-lying areas (less than 10 km from the coast) was also found to explain a large share of losses from high-category TC, whereas remoteness increased the vulnerability. According to the Peduzzi analysis, TCs seem to be more dangerous in rural/remote areas than in cities, which they postulate could be attributed to several factors, such as improved early warning, better infrastructure, and quicker access to external rescue and aid from humanitarian services in urban areas.

Basic health infrastructure is lacking for many communities in the PICTs, especially among remote islands, with significant ramifications for population health. For example, 60% of Papua New Guineans do not have sustainable access to improved water source, and in six PICTs, 50% or more of the population live in houses without sanitation. Only 25% of the people in the FSM have domestic sanitation, and in the Solomon Islands, the figure is 32% (World Health Organization Western Pacific Region 2011). The underlying health problems coupled with their limited local capacity to adapt have intensified the PICTs' vulnerability to a range of potential threats (Hanna et al. 2012). These countries currently face extreme challenges in providing basic health needs for their citizens, and this seriously compromises their capacity to finance additional climate change adaptation strategies. Mounting an effective response to adapt to climate change will therefore require assistance from donor countries, and PICTs welcome this.

Although the need for adaptation to climate change has been recognized via regional and international initiatives, practical adaptation measures remain small in number (Barnett and Campbell 2010). In 2001, Barnett argued that uncertainties with regard to anticipated climate change impacts on PICTs were hindering policy making (Barnett 2001). A decade later, despite increasing evidence and (incipient) awareness of risks to human health and the quickening pace of climate change, global policy action continues to fall well short of what is required to protect the most vulnerable. Few regionally contextualized studies or detailed analyses have been conducted in the Pacific region to confirm what real health risks of climate change exist for these communities. Addressing this lack of information is critical to the development of well-targeted adaptation strategies by PICTs (Hanna et al. 2012).

Effective adaptation strategies are expected to produce better outcomes with respect to both the biogeophysical conditions (the living environment) and the socioeconomic well-being of PICTs' populations. These constitute 'no-regrets' policies (Intergovernmental Panel on Climate Change 2007), as notwithstanding climate change, strong arguments exist to justify such investments, for example, weather-proofing water and sanitation supplies. Climate adaptation investments that increase underlying population health also boost resilience to cope with future climate and other risks.

1.14.8 Case Study: Food Security – Linking the Food, Nutrition, Health, and Climate Nexus in Vulnerable Countries – The Pacific Islands

To summarize, the previous sections mapped the determinants of vulnerability of the Pacific Islands to their climate and future extremes. Climate change is associated with shifts in climate patterns. This shift is composed of a background level of global warming and a trend toward alterations in precipitation events and climatic extremes. These extremes can be periods of intense heat, protracted droughts, or intense storms (TCs/typhoons), which are associated with strong winds, extreme rainfall (hail or snow), and high sea surges. Intense cold spells will also occur in certain regions, as experienced by Europe in early 2012. The severity of the weather that occurs at a particular location and the degree of shift in climate patterns determines the intensity of exposure. Vulnerability therefore is the combination of the climate impacts and the capacity of the community to protect itself and recover from the damage or interruption to services arising.

The following sections of this chapter explore the ramifications of human health arising from climate-related interruptions of food supplies and how this can carry ripple effects through subsequent generations.

1.14.8.1 Food and Climate

Communities develop their lifestyles, agriculture, and cultural practices in response to their natural environment. Dietary staples provide an example of environmental influences on cultural behaviors. People living in high-rainfall areas tend toward diets based on rice, whereas populations from drier regions consume wheat or durum. Although these cultural practices may be enduring, they are not static over generations. Ecosystems exist in a constant state of flux, responding to natural and human-induced interventions. Local inhabitants finely attune their practices in response to these changes and to accommodate their usual range of climate variables, including the extreme fluctuations that occur infrequently.

Long-term shifts in regional weather, hydrology, and soil structure bring relative benefits or disadvantages to certain species of plants and animals, and these pressures of relative advantage underpin the process of evolution. Under normal circumstances, this is a slow and barely discernible process. The rapid pace of climate change will create ecosystem disruptions that are too 'sudden' for smooth ecosystem adaptation. Species need many generations to fully adapt to changes. Those with slow reproductive rates and small numbers of offspring need hundreds of thousands of years. Those unable to thrive in the new environment will decline in numbers. Estimates suggest that even if global temperatures increase by only 2 °C, biodiversity will be significantly diminished and up to 20–30% of species could face extinction.

Humans have managed to inhabit most of the earth's landmass under vastly diverse environments. This success is directly attributable to humans' ingenuity, adaptability, and capacity to optimize conditions and manipulate the environment to suit their survival needs. Long-term survival success of a population is determined by their capacity to provide for their life-sustaining needs, that is, to develop effective resource utilization and management. Throughout human history, the most successful societies have expanded this practice to develop empires, achieved through the accrual of advanced technologies. This advantage facilitated travel and the capacity to exert influence and reap resources from other areas, usually from less technologically advanced societies. Over time, this additional wealth allowed for the further development of complex cites and self-sustaining urban environments, with food and water resources pouring in from outside, through a system of organized trade.

Societies without advanced technological development have been forced to sustain themselves on their own local resources and trading spare resources for the additional goods and services needed. Power imbalances determine the terms of trade, and smaller, weaker societies tend not to be in a position to force favorable terms. In the modern era, international aid programs have evolved to help address some of these inequities, but these relationships remain tenuous because of the underlying power imbalances. SIDS have not enjoyed the opportunities for power and wealth accumulation as *empire states*; indeed, smaller nations have often lost considerable wealth to powerful nations.

Disruptions in customary rainfall patterns will have a powerful effect on reliability of food production.

Despite the trappings of wealth enjoyed in developed nations, the *fundamental* necessities of life are not – as is increasingly assumed – access to cars, computers, or plasma television screens, but rather food, water, air, and shelter. Civil society and peace are also regarded as necessary, to assure longevity in harmony and a rights-based method of sharing resources, ideally in a fair and equitable manner (UNICEF & Innocenti Research Centre 2008; WHO Regional Office for Europe 1986). Climate change threatens to interrupt the supply of all these basic necessities, and hence threatens human survival. As outlined in Chapter 2.5 Role of Engineering Plants for Abiotic Stresses (Biodiversity Loss and Ecosystem Function), food and water are ecosystem services and their provision depends on the regional natural environment, as determined by climate (the range and variability in temperature, wind, sunshine, rainfall, and humidity), water availability, terrain, and soil quality. Article 1 of the United Nations Framework Convention on Climate Change (UNFCC) defines adverse effects of climate change as the link between ecosystems and human health and well-being.

> 'Adverse effects of climate change' means changes in the physical environment or biota resulting from climate change which have significant deleterious effects on the composition, resilience or productivity of natural and managed ecosystems or on the operation of socio-economic systems or on human health and welfare
>
> Article 1 UNFCCC (UNFCCC 1992)

The optimal food-growing conditions consist of a balance of sunshine in a moderate temperature range and regular rainfall, yet with an absence of damaging storms. Societies with access to large tracts of fertile land in these ideal climatic conditions and an equitable system of distribution of agricultural goods are most fortunate. Access to regular water supplies is dependent on regular rainfall, on a landform that allows for collection and delivery, such as valleys for damming and rivers for transport. Delivery to the point of use requires technology and sufficient wealth to construct the necessary infrastructure, canals and irrigation systems to augment rainfall in agricultural regions, and wells or a system of pipes and purification plants to supply domestic needs. Without this infrastructure, people must live close enough to a river or well and have the means to transport personal requirements. In the absence of purification, the risk of contamination and disease is high.

In general, the more removed from ideal agricultural conditions, or technology to overcome environmental shortfalls, the more tenuous is the access to regular supplies of the basic necessities of food and water and the greater is the dependence on alternative methodologies, such as accessing external supplies via trade. Populations living in marginal environments, and without financial wealth and capacity to override their shortfalls, are extremely vulnerable to climate change, considerably more than wealthy countries in ideal agricultural environments.

The lack of infrastructure clearly has not precluded human settlements growing food, and this again testifies to human ingenuity and adaptive capacity. However, human history testifies that both long- and medium-term climate changes have often destabilized civilizations (McMichael 2012), delivered primarily via food shortages, consequent hunger, disease, and sociopolitical unrest. The drought-famine-starvation nexus has been the main, recurring, and serious threat to health and has precipitated large-scale migrations (Fust et al. 2009).

Trade allows for international food redistribution, and this becomes critical when climate conditions create shortfalls. In 2008, 2010, and 2011, climate disruptions occurred in many regions: a heat wave in Russia; droughts in the Horn of Africa, Russia, China, and Brazil; and flooding in Pakistan and Australia. Global food yield reductions escalated prices (Oxfam Australia 2011). Vulnerability to these effects falls acutely on the poor because of their limited capacity to absorb price rises (Fust et al. 2009).

Climate science is predicting the end of the climate stability characteristic of the Holocene period, which provided ideal conditions allowing agriculture to evolve and flourish. Disturbing this albeit dynamic balance will bring interruptions to food supplies and a range of negative consequences for human health and welfare. Above a global temperature increase of 1.5 °C, agriculture in all regions will be vulnerable to climate change. Global food production potential is threatened at +1 °C local temperature change and can accommodate no more than +3 °C before beginning to decline in all regions (IPCC 2007b). Humans cannot divorce themselves from the ecosystems that support them. Food and water supplies lie at the core of this dependence. Societies that face the greatest and most immediate threats to climate change are those that are currently unable to be self-supporting in their food needs, whose food and water supplies are already precarious, or whose food and water harvesting regions are at particular risk from climate change and longer term change, such as through sea level incursion. In this context, Pacific Island nations are especially vulnerable to the effects of climate change, disasters, and the slow insidious impacts.

1.14.8.2 Linking Vulnerability to Health

The impacts for communities are unlikely to be felt as singular linear pathways in the way that researchers tend to examine cause and effect, but rather as compounding layers that overlay, interact, and exacerbate the pressures. It is possible for some of climate–health interactions to have negating or ameliorating effects; however, climate change impacts are likely to be primarily negative and cumulative (McMichael and Woodruff 2002). In some instances, these may result in multiplicative effects on societies and bring catastrophic outcomes.

We have discussed that air, water, food, and shelter are the minimum requirements for health, well-being, and, indeed, survival. It has been understood since the times of Hippocrates (and possibly beforehand) that when access to all these is insufficient, or sources are contaminated, then ill-health ensues. Health, manifested as health status, is therefore an *outcome* of a person's access to these fundamental health determinants. Yet their provision lies outside the formal health sector and so are commonly regarded as 'externalities' to health. The role of the formal health sector, particularly hospitals and doctors, is seen as not delivering these basic health prerequisites, but rather, as striving to reverse the disease or ill-health precipitated by deficits in these external factors.

Climate science is projecting that changing climate trends will affect air quality, water quality and quantity, and shelter (IPCC 2007a). Food security will also be impacted. Food is central to good health, and yet despite this criticality, and decades of advances in food production and distribution systems, universal access to sufficient amounts of nutritious food is still not achieved. In 2009, there were over 1.2 billion people who were undernourished. The 2010 data suggest that 925 million people are undernourished, which represents 13.6%, or 1 in 7 of the estimated world population of 6.8 billion (World Hunger Education Service 2012). Nearly the entire undernourished are in developing countries.

A reliable food supply is required for populations to flourish and grow, and agricultural yield is climate dependent. Approximately 11 000 years ago, in many parts of the world, villages and towns almost simultaneously emerged alongside developments in agriculture. This could only occur when advances in farming methods reached a stage that enabled food production surplus to one's domestic needs. This timing also coincides with a period of relative stability in the climate, where the average global temperature had warmed to and then largely remained within a 0.6 °C range of 14.6 °C (IPCC 2007c). This temperature and stability were not only unusual but also proved ideally suited for agriculture and allowed for the production of reliable yields and the evolution of villages and towns.

Since that time, increasingly urbanized and technical societies have shifted away from subsistence or self-catering lifestyle toward complex food systems, where access to sufficient nutritious food supplies becomes less dependent on personal endeavor and more dependent on an array of sociopolitical and economic factors, which can be distorted and manipulated. In keeping with this trend, more recent shifts from domestic farm ownership and sales via local markets to national or corporate enterprises and food distribution giants, access to food becomes politicized and is intertwined with trade and national powers (Dixon et al 2009).

The small size, both in terms of global economic influence and local geography, therefore limits the adaptive capacity of states such as the PICTs. Coupled with their high exposure, sensitivity, and high potential impacts, this makes PICTs extremely vulnerable. The following case study demonstrates this vulnerability, its complex nature, and how factors reinforce each other to exacerbate the risk of poor health outcomes.

1.14.8.3 Food Insecurity: A Climate Change Risk

Food security therefore serves well as a case study to depict climate pressures ultimately affecting health outcomes and the interlinking of environmental forces, vulnerability, and complex socioeconomic and political filters. This case study outlines the complex systems network underpinning the environment, the food–health nexus, and the long-term ramifications of these influences. Starting from an examination of vulnerability, inability to withstand shocks (be they climate or economic in origin), and food insecurity as food and fuel prices increase and yields fall, we explore the impacts on vulnerable subgroups, at the domestic level, the effects on nutrition and health (maternal and child), and the ultimate capacity to contribute to society and its economic status. This sets up a feedback loop as a poverty trap.

Vulnerability to both climate change and food insecurity is strongly linked with poverty. The poverty and vulnerability experienced by PICTs reflect the stresses placed by a wide range of factors on these societies. According to the AusAID the factors are as follows:

- Weak economies – vulnerable to economic shocks and not providing sufficient jobs.
- Increasing urbanization – loosening the ties within extended families and leading to the creation of squatter settlements with greater dependency on rural areas.
- High susceptibility to natural disasters – stretches the resilience of families, communities, and states.
- Interethnic conflicts – weakening social cohesion and the state (Kidd et al. 2010).

The Commonwealth Vulnerability Index (Atkins et al. 2000) combines vulnerability to both economic and natural shocks and ranks Vanuatu, Tonga, Kiribati, and Samoa among the five most vulnerable states worldwide. In addition to climate change, PICTs are also vulnerable to natural disasters; for example, those situated on or near active fault lines are susceptible to earthquakes and devastating tsunamis, which take a heavy toll on development progress. The tropical climate in many PICTs makes them also vulnerable to landslides, especially in areas that have been logged, and epidemics.

1.14.8.4 Food Insecurity through Economic Vulnerability

Vulnerabilities associated with macroeconomic shocks and natural disasters are neither evenly distributed across the globe nor evenly distributed within countries. Their impacts fall disproportionately on the poor on whom the effects may be cumulative and irreversible, and the inequality (measured as the Gini coefficient) is worsening (Urbano et al. 2010). Developing countries, especially small countries with limited resources, have little reserves to rechannel resources for rebuilding. Owing to their limited power in trade negotiations, they are at the mercy of powerful trading partners, which can force compromises to their nation's best interest. Indeed, they are heavily dependent on these partners for aid and must contend with the uncertainty that aid may not always be (1) available, (2) timely, or (3) appropriate to needs. In the situation of increasing climate disasters and continuing global financial crises, an increasingly likely scenario is one in which foreign governments may be pressured by their home constituents to focus on internal reparation and rebuilding at the expense of international aid generosity or meeting their aid obligations.

In 2012, the PICT's demand for food is being increasingly serviced by imports. Basic staples such as rice and wheat for flour have become key substitutes for traditional diets and are now central to the Pacific Islander's daily diet (FAO 2008). Deteriorating terms of trade, rising external debts, and inflation stifle the capacity of Pacific Islanders to adequately meet their nutritional requirements from imported food alone. Ramifications of both the current global economic crisis and the 2008 global food crisis have therefore been felt keenly by the PICTs, through declining tourism income and falling amounts of remittances (and falling values of those denominated in US dollars) and depreciating values of internationally held trust fund portfolios (Kidd et al. 2010). Their economies are weakening, and living standards are falling.

Vulnerability assessments carried out in 2009 and late 2010 indicate that the more remote and import-dependent Pacific Island economies of Kiribati, FSM, Republic of the Marshall Islands (RMI), Tuvalu, and Tonga are particularly exposed to the economic burdens of higher global fuel and food prices. Fiji, Solomon Islands, and Vanuatu are also vulnerable because of high inflation and structural issues and their geographically dispersed population (UNICEF 2011a). The particular vulnerability of Tonga and Vanuatu lies in their high frequency of natural disasters, and the resultant effects on agricultural production, and very limited social protection activities. Conversely, the economies of the Cook Islands, Niue, and Samoa are among those of the better performing Pacific nations, with consistent economic growth, impressive social development, and good progress toward achieving their MDGs, especially MDG 1 on eradicating extreme poverty and hunger (UNICEF 2007), yet there is great disparity in income growth both between and within countries.

Since the rapid escalation in food prices during the 2008 global food crisis, prices fell only briefly. The Food and Agriculture Organization (FAO) generates a global Food Price Index (FPI) to enable interannual comparisons. In June 2011, the FPI was 39% higher than in June 2010, and only marginally less than its all-time high of 238 points in February 2011, and cereal prices were 71% higher than in June 2010 (FAO 2011). The steady rise in food prices in the Pacific has caused widespread concern, for example, in Kiribati (with a GDP per capita of US$1142 in 2009), prices for staples such as rice increased from AUD$16 per 20 kg bag in 2006 to AUD$21 in 2008 (UNICEF 2011a). Vanuatu populations have been exposed to price increases ranging from 40% to over 100% for staples such as taro, banana, and yams (UNICEF 2011c). According to the regional sentinel monitoring system, a majority of vulnerable families surveyed in six Pacific Island countries reported increased economic stress in meeting food expenditure because of rising food prices, as the cost of some staple food items were up by as much as 50–100% since 2009 (Miskelly et al. 2011). Households are forced to spend 39–50% of their budgets on food (Food Secure Pacific Working Group 2010).

Compounding the food stress imposed by import price rises is decreasing local food yields. Some agricultural crops in Vanuatu are already showing signs of stress under current climatic conditions. The food price increase takes the greatest toll on the poorest households because of their higher relative expenditure on food. Food stress is highest among the urban poor, whereas rural poor have a higher likelihood of supplementing their food supplies by resorting to subsistence farming (Miskelly et al. 2011). Food poverty indicates the inability of households to feed themselves. Household surveys that have calculated the proportion of people falling below food poverty lines is high: 16.6% of the population in Palau, 11% in FSM, 10.6% in the Solomon Islands, 7.4% in Vanuatu, and 4.9% in Kiribati (Kidd et al. 2010).

There are significant differences across countries, with import dependency ranging from 36% in Kiribati to over 80% in Palau (Parks and Abbott 2009). These figures represent import dependency at the national level; however, significant variation also exists within countries, especially between urban centers and rural areas. The share of total expenditure on food and transport in urban area ranges from 35 to 40%, whereas the range is less in rural areas, from 20 to 25% (Global Study on Child Poverty and Disparity 2009). Urban dwellers who rely mainly on purchased foodstuffs are disproportionately more affected than rural households who live outside the cash economy (McGregor et al. 2009) and are therefore more at risk of undernutrition and consequent ill-health. Having no significant food exports, the inhabitants of Polynesia and the atoll microstates are similarly vulnerable because of their dependence on imported food.

Within the vulnerable urban groups, those most likely to experience the greatest degrees of hardship and poverty will be (1) the very young, (2) the very old, (3) people living with disabilities, (4) those who have no source of regular income, or (5) those with no access to adequate land on which to grow food for consumption and/or sale (Parks and Abbott 2009). Households headed by women and the elderly will be very vulnerable. It follows then that children living in female-headed households are likely to be especially disadvantaged.

Owing to the strong emphasis on caring and redistribution that exists within the extended family system, poverty in the Pacific Island context does not necessarily mean outright hunger or destitution. However, the poor face a continuous struggle to meet essential daily/weekly living expenses, particularly those that require cash payments. Furthermore, the subsistence sector, which in the past has played an important role in sustaining livelihoods in the Pacific Island economies through difficult times, is having a diminishing role. The trend toward urbanization is eroding the traditional support networks that for generations have helped safeguard food security in times of hardship (Hanna et al. 2012).

High food prices accentuate the vulnerability of the rural and urban poor. Eroded purchasing power inevitably leads to difficult decisions and a deterioration in the amount and quality of food consumed. A sentinel monitoring system conducted in 2010 (UNICEF 2011a) revealed that a majority of vulnerable families, particularly those in urban areas, were experiencing increased economic stress in meeting food expenditure because of rising food prices and the global economic crisis. Food stress was reported by 63% families in Solomon Islands, 77% in Tuvalu, and 54% in Kiribati (UNICEF 2011a), and this stress forced changes to the type and quantity of food consumed as well as to the cooking methods.

Most PICTs have an extraordinary dependence on fish for food security because of limited access to other sources of animal protein, particularly in rural areas (Bell et al. 2011a,b). The world's oceans and fish stock have become increasingly under threat from ocean acidification, rising seawater temperatures, ocean deoxygenation, sea level rise, pollution, and the overuse of marine resources (overfishing) (Noone et al. 2012). The average acidity of the upper ocean has already declined by around 0.1 pH unit, which represents a 30% increase in acidity since the industrial revolution. Three of these interacting factors, warming, acidification, and hypoxia, will cause substantial changes in marine physics, chemistry, and biology (Plymouth Marine Laboratory 2012). Many PICTs are heavily dependent on their fisheries resources for economic development, government revenue, food security, and livelihoods and are vulnerable to any change in the status of these resources (Bell et al. 2011a,b).

Through rising food prices, fresh or frozen meat and fish, now considered a luxury, have been predominantly replaced by cheaper alternatives such as tinned fish, noodles, and turkey tails, and where able, vulnerable families are relying on backyard gardens and are consuming much less fresh protein (Miskelly et al. 2011). Among the poor, rice, flour, and milk were reportedly considered expensive, as women sought cheaper substitutes or cooked with them only rarely.

Households commonly used food rationing to keep food costs down, and the poorest families reported living on tea and starchy basics. The report revealed that because of their lower cultural status, children and women often are not prioritized at the meal table and may only consume one or two meals a day. Another practice commonly reported was for children to go without breakfast and eating meager or no lunch at school (UNICEF 2011a).

As diets become more and more restricted, they become increasingly deficient in micronutrients, with potentially pernicious long-term consequences for growing children and pregnant women. Malnutrition, including micronutrient deficiencies, is already common across the Pacific, and the changes in household food consumption patterns brought about by the economic crisis is likely to have increased these problems (Parks and Abbott 2009). Despite a proportion of the population still relying on traditional subsistence agriculture, the food insecurities faced by many Pacific Island countries and households will further exacerbate if impacts of the economic crisis and high food prices do not abate. The World Bank predicts an increase in poverty as families face a triple squeeze from falling incomes and remittances, rising costs, and shrinking public expenditure, including aid (Rawe et al. 2012).

1.14.8.5 Child Health

There is considerable evidence demonstrating that food shortages in childhood can have important and sometimes permanent cognitive, motor, socioemotional, educational, and economic repercussions across the life course (Parks and Abbott 2009). Food-insecure children have twice the odds of having only 'fair or poor' health, and their odds of being hospitalized are almost one-third larger than food-secure children; the greater the severity of food insecurity, the greater is the health risk (Cook et al. 2004). A strong link has also been established between poor maternal nutritional status and low birth weight and increased infant and childhood morbidity and mortality (Amuna and Zotor 2008). Poor mothers are more likely to die in childbirth (Inter-Agency and Expert Group on MDG Indicators 2008); the nutritional state of the mother and fetus is therefore critical, as the impacts of undernutrition linger for the life of the child and the diminishment in their health and earning capacity flows on to subsequent generations.

Prenatal environment triggers developmental changes in the endocrine, organ, and physiological characteristics of the fetus that may persist after birth. The list of postnatal traits shown to be influenced by the prenatal environment has expanded to include such important functions as immunity, reproductive function, growth rates, and muscle mass (Prentice and Goldberg 2000). Furthermore, the undernourished pregnant women experience metabolic suppression of immune system synthesis, which contributes markedly to the high rates of perinatal and infant mortality seen in many poor countries (Amuna and Zotor 2008). An undernourished mother suffering nutritional stress has intrauterine growth restriction, as a physiological coping mechanism to preserve her own health, and delivers a low-birth-weight baby. The early and later life consequences for her child include type 2 diabetes mellitus, hypertension, and hyperlipidemias (Lucas et al. 1999), all of which are prevalent and rising rapidly in the many Pacific communities (SPC 2010). Children who are compromised at birth have a higher susceptibility to diseases such as diarrheal diseases, malaria, etc.

The percentage of Pacific Island children born with a low birth weight (<2500 g) varies from 3% in the Cook Islands to 18% in FSM. Another key indicator for childhood undernutrition is the proportion of children classified as underweight when under 5 years. In the Pacific, the figures range between 1.6% in Tuvalu and 16% in Vanuatu, and in Vanuatu, 20% of children under 5 years are stunted (Parks and Abbott 2009). Globally, it is estimated that stunting, severe wasting, and intrauterine growth restriction together are responsible for 2×2 million deaths and 21% of disability-adjusted life years (DALYs) for children younger than 5 years (Black et al. 2010). Stunted children may never regain the height lost as a result of stunting, and most children will never gain the corresponding body weight. It also leads to premature death later in life because vital organs never fully develop during childhood (Finnigan and Luetz 2009). Results indicate that children living in households belonging to the lowest wealth index quintiles are more likely to be underweight and children from households within the richest quintile are more likely to be overweight, which carries another set of health risks. Stunting remains throughout life. Stunted women have a 95% higher need for assisted deliveries when they reach childbirth, and if operative delivery services are not available, the lives of the mother and child are at risk (Black et al. 2008). Many remote islands have limited obstetric services, and many poor are unable to afford travel to major centers for health care.

Deficiencies in micronutrients, such as calcium, iodine, the B vitamins (especially folic acid and vitamin B_{12}), and vitamin D, result in health problems for maternal and child health (Black et al. 2008). Zinc deficiency in children results in increased risk of diarrhea, pneumonia, and malaria, whereas deficiencies in iodine result in goiters, congenital hypothyroidism, and developmental disability (Black et al. 2008). Vitamin A deficiency reduces immune system functioning, which places the child at a greater risk of succumbing to infectious diseases (Rawe K et al. 2012). Iron deficiency anemia is another significant public health concern for the Pacific region. Figures are not available for all countries; however, where data exist, 6 of 10 children are anemic, and for Vanuatu, 34% of children aged 6–59 months are anemic (Parks and Abbott 2009).

Many other health problems among Pacific Island children result from undernutrition. Every year, around 18 000 children under 5 years of age die (13 000 in PNG, 2500 in Timor-Leste); four of five of these children are under 5 years of age (Parks and Abbott 2009). Maternal mortality is also high, which leaves her other children without a mother, which further jeopardizes their health. Social services, such as disability services, are underresourced, especially across the outer islands and remote areas. It is estimated that up to two-thirds of childhood disabilities are preventable, thus there is a lot of scope for improvements in prevention of disability, particularly in safe motherhood and deliveries, nutrition, water, and sanitation (Tavola and Whippy 2010).

Diarrheal diseases are already the most common cause of illness and the second highest cause of death of children under

5 years of age, causing as many as 1.6 million deaths (17%) per year (WHO 2009). It is estimated that 80% of the mortality from diarrhea is attributable to unsafe water and lack of sanitation (with nearly 90% of the global burden of diarrheal disease caused by the lack of access to safe water and sanitation) (Parks and Abbott 2009).

1.14.8.6 Climate and Food and Health

The relationship between rainfall and diarrhea is well established, both in terms of incidence (higher number of cases related to reduced water availability) and the mortality rates of children under 5 years (WHO 2011). Climate change is projected to bring greater variability in rainfall patterns (Australian Bureau of Meteorology and CSIRO 2011b). Both excessive rainfall and rainfall shortage can be problematic for human health. Heavy rainfall contaminates drinking water supplies, whereas water shortages lead to water conservation, reuse, and sharing, which risks multiple mechanisms for contamination. Lack of access to clean water exacerbates the burden of diarrheal disease and increases the risk of death and disability, especially in children who need more water per body mass compared to adults.

Water security, defined as regular access to adequate quantities of clean water, requires water availability (rainfall) and expensive infrastructure to purify and deliver to the end users. Developing countries face many challenges in delivering water security to their entire population. Children are especially vulnerable to infections that cause diarrhea (Parashar et al. 2003) not only because their immune system is less robust in fighting infections than that of older people but also because their behavior (playing on the ground and hand to mouth behavior) increases the likelihood of exposure to infectious agents from water and other people, especially family members and other children. Nutrient absorption from the diet is interrupted during bouts of diarrhea, hence diarrheal diseases further compromise the nutritional status of the child and increase susceptibility to other opportunistic parasitic infections. Malnutrition becomes a double burden, as the reduced resistance to disease exacerbates the condition (WHO 2009). Climate change will directly affect the risk to children from diarrheal disease if the provision of adequate and safe food, water, and sanitation are compromised through changing rainfall patterns.

The mortality and morbidity risks from environmental conditions are 44% higher in children under 14 years than in the rest of the population (United Nations Secretary-General's High-level Panel on Global Sustainability 2012). By virtue of their early stage in development, children and especially very young children are at greatest risk of injury, disability, and death from the consequences of the changing climate system (Hanna 2011). With their dependence on others for sustenance, nurturing, protection from infection, and physical harm, the susceptibility of children to threats is increasing (WHO 2009). Overwhelming scientific evidence suggests that the three greatest killers of children – malnutrition, diarrheal disease, and malaria – will be exacerbated by climate change (Schneider et al. 2007). The risk of harm is greatest for children living in developing countries, because of the dual disadvantage, that is, extreme climate effects and because poverty limits their ability to respond.

Socioeconomic situation can place further barriers to a poor child's prospects. In situations of national poverty, funding cuts to schools lead to declines in education quality and the higher costs are transferred to parents. In extreme domestic poverty, one of the difficult decisions can be to withdraw children from school because of inability to afford the direct schooling costs or requirement of children to supplement their family income. Often, girls' education will be sacrificed, and if in later years she becomes a sole mother, her children are destined to remain in the poverty trap. Malnourished students perform poorly at school, and this also predisposes the child to a future with restricted economic opportunities. A poorly nourished generation deprives a nation of its most valuable resource, human contribution to society, and the economy. Speaking on these effects of climate change in Kiribati, His Excellency Mr. Anote Tong, President of the Republic of Kiribati, claimed " Climate change is eating away [adolescents'] future and putting their physical and mental development at risk" (UNICEF 2011b).

Climate change will deliver many challenges. Some are already beginning to emerge, climate science suggests more, and much more is to follow. Countries, particularly vulnerable countries, need their populations to rise to the challenge, and to do this, they need to optimize the health of every child.

1.14.9 Summary

The vulnerability of Pacific Island countries to climate change is driven by a number of determinants (Pachauri et al. 2007; UNFCCC 2007). Essentially, the two key determinants, (1) projected *levels of exposure* to intense forces of climate change and (2) *sensitivity to those exposures*, are both high. Their sensitivity arises not only from a range of geophysical attributes but also, for many islands, from their preexisting vulnerability to shocks of any nature due to challenges of resource limitations, which hampers their capacity to initiate large-scale and complex responses. This combination puts PICTs into the highly vulnerable category.

Health impacts arising from a changing climate will not be distributed evenly around the globe (Adger et al. 2006). In the short term, there will be some winners and many losers, based on the variable exposures and vulnerabilities across the globe.

When conducting a vulnerability analysis for a specific location, it is important to understand existing vulnerabilities, threats, challenges, coping capacities, and potential strengths. Step two involves an assessment of the society's capacity to prepare for, withstand, and minimize harm and then recover from those effects when they do occur. The third step involves identifying the trigger points, beyond which significant harm will emerge and potentially overwhelm response capacity. Examination of the likelihood or timing of encountering such scenarios is the next step, which serves to prioritize strategic planning.

A worst-case scenario is one in which (1) climate forces will be strong and (2) community resilience is relatively weak. Coexistence of these pressures at any level is extremely risky and renders the populations especially vulnerable, and the resultant impact will be proportional to the capacity of the community to withstand and rebound from the climate challenges confronting them. Where the combination of these pressures is particularly intense, a high likelihood exists that the associated outcome will be catastrophic and potentially lethal to community well-being and ultimate survival.

To summarize, the case of food security in small Pacific Island countries clearly demonstrates how climate change affects highly vulnerable developing countries. The health of the populations is further compromised through the mechanism of intensifying food (and water) insecurity, which renders them even more vulnerable and less able to escape the poverty trap. We have seen how Pacific Island countries are vulnerable to natural disasters that can cause temporary food insecurity. In the past, traditional smallholder farming systems have proved to be robust, productive, and protective in the face of adversity. These systems need to be supported and strengthened to assist Pacific Island countries to meet the challenges of increased food prices. Food and water security are health issues and must be protected to secure human health.

Nutrition is one of the most significant factors determining risks to the health of women and children. Its importance extends beyond ensuring survival of an individual. Nutrition provides the source from which future social and economic opportunities flow for generations to come. Investing in children and women is necessary to protect population health now and into the future. Single approaches are unlikely to succeed when people live in a multithreat environment. Protection against climate change should be part of a suite of actions that optimize public health, which includes the expansion and the subsequent ongoing maintenance of essential health and social services for children and women (health, education, HIV prevention, and protection from abuse, violence, and exploitation). This needs to occur against a background where economic challenges are likely to persist and be exacerbated by climate change. Per capita health expenditure may eventually diminish, as competing budgetary demands to fund recovery from natural disasters and rebuild infrastructure consume an increasing proportion of total government expenditures. Countries letting health slide are counterproductive, and maladaptive, as underinvestment in fundamental public health compromises nation's future security and prosperity; these are dependent on a healthy population.

1.14.10 Adaptive Strategies

Basic strategies to enhance population health include

- supporting national agriculture;
- implementing universal improved water supplies and domestic sanitation – for urban and rural dwellers;
- provision of universal maternal and child health programs;
- provision of micronutrient supplements for children (vitamin A and zinc);
- micronutrient fortification (iron and salt iodization);
- expanded immunization coverage for children;
- deworming and other nutrition programs at school;
- introducing schooling fee structures that allow for education of all children;
- increasing and improving girls' schooling;
- implementing community-based nutrition promotion;
- providing support for women's reproductive role (and family planning);
- providing national malaria prevention and treatment;
- HIV combination prevention; and
- introducing microfinance to support the poor to become food secure.

More systemic strategies include

- a coordinated response at national, regional, and country levels;
- development partners continuing to work together;
- finding ways to retain and health personnel to ensure delivery of primary health care;
- sustainable health systems;
- seeking commitment of continued long-term financing of climate change activities; and
- strengthening monitoring, surveillance, and evaluation of public health programmes.

This list is intentionally broad, and yet is not exhaustive. It deliberately takes a health perspective to food security, whereas other food security reports focus on food production. Here the parenting–child health links are prioritized to provide an indication of the breadth of influences that can affect food security and boost resilience to climate change.

Good advances have been made in other sectors over recent years, largely as a result of issues gaining sufficient profile to garner solid investment and multilateral cooperation. Ministers attending the 7th Pacific Health Ministers Meeting in 2007 in Vanuatu called for a Pacific Food Summit. The following year, Pacific Island Forum leaders made food security a priority in the Pacific, and in 2009, Ministers of Trade, Agriculture, and Health endorsed the concept of a Pacific Food Summit at their respective regional meetings. The Pacific Food Summit was held in Port Vila, Vanuatu, in April 2010 and attracted more than 170 people from the 23 countries attending (Food Secure Pacific Working Group 2010). A key to its success was the shared commitment and breadth of involvement. It was genuinely interdisciplinary in nature and included all PICTs. Ministers and senior policy makers from Agriculture, Health and Trade as well as representatives from the food industry, community organizations, faith-based organizations, consumer groups, academia, and regional and national organizations attended. The purpose of the summit was to enable regional action on food security.

More recently, noncommunicable diseases have been identified as a priority issue for joint action among the PICTs. A 2-1-22 Programme has been devised that combines 2 donor organizations, 1 goal, and 22 PICTs to address the shared challenges. There is a clear and urgent need for development of a similar overarching framework for addressing the pressing climate change challenges facing the PICTs. Precedence has been set with these two existing programs, and a framework model of cooperation has been established. The model could be applied to other vulnerable states beyond the Pacific.

Such strategies require significant donor investment to appropriately resource the activities. Neighboring developed countries have international obligations under the UNFCCC to assist developing countries adapt to climate change. The lives of millions of Pacific Islanders, and populations in other vulnerable countries, depend on this international support. The UNFCCC recognizes the special situations of the LDCs and introduced National Adaptation Programme of Action (NAPA). Developed countries that have signed the Kyoto agreement contribute to the fund and manage projects within specific LDCs. Individually funded projects are also beginning to emerge, but the task ahead, especially for the world's LDCs, is enormous and growing.

Many PICTs are progressing their NAPAs, and although the profile of health among climate change strategies has been expanding, there is more to be done. Making the connection between human health and climate change has been slow in the donor organizations. Climate and a changing climate are deeply human issues, as the climate determines the provisioning of human necessities, such as food and water. Climate extremes can destroy these ecosystem services, plus our homes, businesses, and infrastructure, and dismantle sociocultural systems. A healthy population is a key element of adaptive capacity to minimize negative impacts. Therefore, maintaining optimal health determinants; ensuring whole population access to sufficient food, water, clean air, and shelter; and providing equitable access to effective health care and education are the necessary ingredients to securing the health of current and future generations and central to reducing vulnerability to climate change and other shocks.

1.15.1 Introduction

Climate and long-term change is increasingly recognized as a critical issue for society, and governments are asking questions about how to allocate scarce resources in order to minimize adverse impacts. A critical component of answering these questions requires an assessment of vulnerability to the changes that are projected to occur. People in Africa are particularly at risk from climate factors, because of exposure combined with low adaptive capacity. In addition, climate coincides with other stressors that affect the livelihoods and well-being of people. On the one hand, long-term changes in weather patterns would bring with it changed health risks, while on the other, the vulnerability of people to climate will be affected by their existing health status.

1.15.2 Vulnerability to Climate

Vulnerability is a contested term that has its origins in the natural hazards and food security literature and is now often applied in climate impacts assessments (Adger 2006). However, an evolution in the understanding of vulnerability has occurred over time. In early impacts assessments, focus was placed solely on the risk of exposure of an ecosystem to a hazard. This meant that impacts assessments at that time would refer to the effects of climate on parameters such as crop production and water availability and could thus be defined as biophysical vulnerability or 'outcome vulnerability' (O'Brien et al. 2007). People were only deemed affected because climate would alter the availability of resources on which they depend for their livelihoods.

In biophysical or outcome vulnerability assessments, there was little recognition of the fact that people are different, and just because they are exposed to the same hazard does not mean they will respond in the same way. 'Social vulnerability' may be defined as the ability to anticipate, resist, cope with, and respond to a hazard (Blaikie et al. 1994). Social vulnerability, in contrast to being seen as an outcome, is viewed more as a potential state of human societies that can affect the way they experience natural hazards (Adger 1999; Adger and Kelly 1999; Blaikie et al. 1994). This potential state is in constant flux, reflecting its dependence on the dynamic interaction of a range of economic and social processes that influence the capacity of individuals, social groups, sectors, regions, and ecosystems to respond to various socioeconomic and biophysical shocks (Leichenko and O'Brien 2002; Comfort et al. 1999). The most vulnerable are those who are most exposed to any changes, who possess a limited coping capacity, and who are least resilient to recovery (Bohle et al. 1994). As the particular mix of structures and institutions is typically context-specific, this has also been labeled 'context vulnerability' (O'Brien et al. 2007). Determining projected climate impacts, therefore, reflects not only likely exposure and biophysical, or outcome, vulnerability (of the ecosystem) but also the social, or context, vulnerability of the people.

Given evidence of differential social vulnerability in the face of hazards or broader environmental risk exposure, a number of studies have tried to characterize the determinants that may give rise to vulnerability (e.g., Pelling 2003; Smith 2001; Blaikie et al. 1994). Vulnerability is a function of economic, social, political, environmental, and technological assets. Who is vulnerable to a hazard is therefore determined by the human and physical forces that shape the allocation of these assets in the society (Pelling and Uitto 2001). Defining vulnerability is also dependent on the scale of analysis (Vincent 2007a).

On the large scale, macro-processes are the most important in determining the distribution and production of entitlements. In the well-developed food security literature, famines have been explained on the basis of entitlement theory (Sen 1981), where the distribution and reproduction of entitlements is dependent on the structural factors of the political-economic environment that can either reduce or precipitate entitlement failure (Downing 1996; Bohle et al. 1994; Watts and Bohle 1993). In the case of food and famine, e.g., the political-economic environment refers to the dominant political system and the way it mediates trade, labor, and markets. In the face of exposure to climate factors, some populations will be able to draw on their entitlements to adapt to the risk, e.g., through awareness and preparation, insurance for losses, and diversifying livelihoods. For example, Adger (1999) shows how collective vulnerability (at community level or higher) to

http://dx.doi.org/10.1016/B978-0-12-384703-4.00124-6

extremes in coastal Vietnam is determined by institutional and market structures. In contrast, on the local scale, the role of human agency has a greater influence in access to resources and household-level social status. In such cases, entitlements are socially and spatially differentiated according to factors such as gender, ethnicity, religion, class, and age (Denton 2002; Enarson 2000; Wisner 1998; Cutter 1995).

1.15.3 Climate and Health

Weather patterns, and other aspects of climate, affect human health both directly and indirectly, via biological and ecological processes that influence the transmission of several infectious diseases (McMichael et al. 2003). One of the major health impacts of climate relates to disease burden. The effects of climate on vector-borne malaria and waterborne cholera have been well studied, given that they already pose existing risks in Africa (Boko et al. 2007). Fewer studies have looked at the links between other diseases, such as meningitis, Rift Valley fever, and dengue fever, and climate-related variables (Jansen and Beebe 2010; Anyamba et al. 2009; Cuevas et al. 2007). More indirect effects of climate on health relate to the transmission of human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS), heat stress, and respiratory illness, which are discussed here. Other indirect links of climate and health relate to cancer, mental health and stress-related disorders, zoonotic diseases, and food-borne illness (Portier et al. 2010).

1.15.3.1 Direct Climate Effects on Malaria and Cholera

Malaria is the leading cause of mortality and morbidity in hot and humid African countries (Wandiga et al. 2010). The spread of malaria within Africa is dependent on the susceptibility of the vector (mosquitoes of the *Anopheles* genus) and parasite (*Plasmodium falciparum*) to climate. A close association between malaria epidemics and climate has been contested, but a recent paper that analyzes past climate (temperature and precipitation), hydrological and health data (1961–2001), and socioeconomic status of communities from the East African highlands confirms the link between climate and the incidence and severity of malaria epidemics (Wandiga et al. 2010).

In the absence of good epidemiological information, the association of malaria with seasonal climate patterns is used to map risk areas (climatic suitability for endemism), as in the MARA (Mapping Malaria Risk in Africa Project) model (Grover-Kupec et al. 2006; based on baseline endemism maps from Guerra et al. 2008). A global map of *P. falciparum* malaria endemism shows that of the 1.38 billion people at risk of stable *P. falciparum* malaria, 0.66 million are found in Africa, Yemen, and Saudi Arabia (a proportion similar to those found in south and central Asia). High endemism was also widespread in the African region, where 0.35 billion people are at this level of risk, with 0.20 billion at intermediate risk, and 0.11 billion at low stable risk (Hay et al 2009; based on the MARA data, which includes over 7000 *P. falciparum* parasite rate surveys from around the world).

Since malaria is endemic in much of Africa, changes in climate factors affecting malaria may induce an increase in transmission on the fringes of stable zones, e.g., at higher altitude in the highlands (see, e.g., Tonnang et al. 2010). Additional population at risk from malaria is projected in East Africa (Chaves and Koenraadt 2010; van Lieshout and Kovats 2004), while parts of the northern Sahel may have a decreased risk (Caminade et al. 2011). Adverse effects of malaria spread into new regions are typically higher than where the disease is already prevalent, because of the lack of protective genetic modifications that bring immunity. This applies to morbidity and mortality in both children and adults, as shown by the outbreak of epidemics in the East African Highlands (Lindsay and Martens 1998). In Rwanda, the February 1998 malaria epidemic led to a fourfold increase in malaria admissions among pregnant women and a fivefold increase in maternal deaths due to malaria (Hammerich et al. 2002).

The risk of cholera has been shown to increase with increased temperature and rainfall (e.g., Trærup et al. 2010) and with increased sea surface temperature (Paz 2009). Analyses of precipitation, temperatures, and hydrological characteristics of selected stations in the Lake Victoria Basin show that cholera epidemics are closely associated with El Nino years, and epidemics are also triggered by sustained temperatures high above normal ($T_{\max}$) in two consecutive seasons, followed by a slight cooling in the second season (Olago et al. 2007). A global analysis of cholera data from 1974 to 2005, however, showed that while cholera outbreaks demonstrate seasonal patterns in higher absolute latitudes, closer to the equator cholera outbreaks do not follow a clear seasonal pattern (Emch et al. 2008).

1.15.3.2 Indirect Climate Effects on HIV/AIDS, Heat Stress, and Respiratory Illness

In Africa, an important public health issue is the prevalence of HIV/AIDS. There are also interlinkages between climate and HIV/AIDS, although the pathways are less direct than with vector-borne and waterborne diseases. Climate-related factors might increase the risk of HIV/AIDS through its impact on food (in)security and migration. In Malawi, farmers in two districts at high risk of droughts and floods—Nsanje and Salima—observed how the lack of food and limited income to buy food encouraged women to engage in transactional sex as a coping mechanism, thereby increasing their exposure to HIV infection (Action Aid 2006). Migration is also a common coping mechanism in response to local crisis, which may be precipitated by climate extremes and can also increase exposure to HIV infection (Lurie 2004).

In addition to altering the nature and type of risk of particular diseases, long-term changes in temperature might also affect heat-related illnesses. If temperatures were to increase over Africa, as projected, diseases may expand their reach and death tolls, with more indirect effects on water and food security (Costello et al. 2009). These indirect effects of climate could bring about not only mortality and morbidity but also adverse impacts on the well-being, health, and productivity of working populations (Bennett and McMichael 2010).

Temperature also plays a role in the prevalence of many respiratory diseases, and thus it is not surprising that climate affects these diseases, such as tuberculosis, asthma, and allergies. Although climate has less influence on tuberculosis mortality than some other factors, evidence that warm, damp climates are associated with relatively high tuberculosis mortality dates from the early twentieth century (Morland 1936). The burden of tuberculosis in Africa is high, and there is often coinfection of tuberculosis (*Mycobacterium tuberculosis*) and HIV (Dye et al. 1999). Allergies affecting the respiratory system and asthma can also be affected by changes in climate, which in turn affect the load of airborne allergenic pollens (Ariano et al. 2010; Shea et al. 2008). Both heat-related and respiratory illnesses will have differential effects on vulnerable subpopulations, such as children (Bunyavanich et al. 2003).

1.15.4 Health and Vulnerability to Climate

The relationship between climate and health status is two-way: climate affects disease burden and the health status of the population affects (social) vulnerability to climate impacts. Social vulnerability is a potential state of human societies that can affect the way they experience climate parameters and hazards (Adger 1999; Adger and Kelly 1999; Blaikie et al. 1994). People living with poor health are likely to have greater social vulnerability when exposed to climate threats. This is exacerbated by any long-term change in the average climate of a region, which, unlike extreme events, means that populations will not necessarily have a chance to recover and reduce their vulnerability levels before the next exposure.

Reflecting the chronic nature of the health issue and its widespread prevalence across the continent, in Africa it is HIV/AIDS that has most been studied as the health condition that intersects with vulnerability to climate. It has been shown that the transition to a market economy and the introduction of HIV into the human environment has led to institutional decay in some countries, which, as a result, are more likely to suffer from climate-related health issues (Bloom 2004). Infection by HIV/AIDS makes people more vulnerable to climate threats, as sufferers are less able to cope with reduced food intake and have reduced flexibility in livelihood strategies required to adapt.

Furthermore, for people already suffering from HIV/AIDS, exposure to extreme events such as floods can lead to cholera outbreaks, as they are more susceptible. Similarly, any resulting damage to health infrastructure (including home-based care) may impede their access to antiretrovirals. A study of child malnutrition in relation to the HIV epidemic and drought (crop years 2001–02 and 2002–03) in six countries of southern Africa found a strong correlation between HIV and drought and concluded that the combined effects of droughts and HIV/AIDS could have an even more significant adverse impact on child nutrition in the future (Mason et al. 2005).

1.15.5 A Case Study from Southern Africa

This chapter has shown that the impacts of climate are dependent not only on the climate parameters themselves but also on the characteristics of the people who experience those climate parameters and the assets or resources they have with which they can respond to them.

It is essential to determine the impacts on society of possible changes in climate parameters. Traditionally, science has concentrated on projections of long-term changes in climate using models based on past analogs of climate variability, and then made some suggestions as to how such changes might have impacts on human populations through changing patterns of weather and extremes (McCarthy et al. 2001). However, a limitation of such top-down approaches is their failure to take into account the differential vulnerabilities of human populations to those environmental risks, either through resisting an event or by coping once it occurs (Jones and Boer 2003; Stonich 2000). Moreover, the top-down approach provides, at best, just a subset of possible future regional and local climatic conditions, and improvements in modeling bring with them additional uncertainties due to the greater complexity of processes being modeled (Pielke and Wilb 2012; Trenberth 2010). Essentially, as once dominated the thinking with regards to natural hazards, changes in climate are seen as a problem *for* the society, not *of* the society (Hewitt 1997). Many impacts assessments have thus been impeded by only considering one side of the equation—the exposure (Cutter 1996). In reality, assessing the impacts of climate is inextricably linked with an assessment of social vulnerability.

Assessing social vulnerability is thus an essential component of climate impact assessments. A place-based enquiry was undertaken in one community in Limpopo province, South Africa, chosen for its experience of past climate variability and an example of possible future climate change (Vincent et al. 2011; Vincent 2007b). This area, to the north of the Soutpansberg mountains, is semiarid with a summer rainfall season (November–March). There are high levels of interannual variability, punctuated by regular droughts and occasional floods, most notably in 2000. In terms of human characteristics, the village comprises approximately 700 people in 180 households and has a legacy of natural resource-dependent livelihoods (primarily crop farming), in addition to a small level of formal employment in local towns. The area was formerly part of the Venda homeland. An index of social vulnerability to climate has been developed to compare households at grassroots level in Limpopo province, South Africa, and is explained elsewhere (Vincent et al. 2011; Vincent 2007a,b). Health status is incorporated into the index as a recognized driver of social vulnerability, and this element is elaborated on here (Adger and Vincent 2005).

The index is theoretically determined and is an aggregation of five equally weighted component subindices: financial capital, human capital, social capital, physical capital, and natural capital, based on the Sustainable Livelihoods Framework (for more information, see Vincent 2007a,b). While the structure of the index is grounded in the theory of determinants of social vulnerability, the component indicators were chosen as appropriate to the context for which this particular index was first used (a small, dryland village in Limpopo province, South Africa).

Human capital refers to the skills, knowledge, ability to provide productive labor, and good health that allow people to pursue their livelihood strategies and thus meet their livelihood objectives. Human capital is a function of the amount and quality of labor available in the household, which is dependent on factors such as education, health status, and knowledge. In this way, human capital is also a prerequisite for the transformation of natural capital (such as soil and water in agriculture) and physical capital (such as the use of building materials to construct a house) and for the accumulation of financial capital. Accumulation of human capital is also often seen as an end in itself, as illiteracy and poor health are often regarded as core dimensions of poverty, and overcoming them is a primary goal of development. The human capital subindex, e.g., is a composite of two component indicators: household dependency ratio (ratio of working age adults to youth and elderly) and households with a member suffering from a long-term or recurrent disease (Vincent 2007b).

To a certain extent, the progress that South Africa has made in tackling typical rural diseases, such as typhoid and cholera, is offset against the increasing incidence of HIV/AIDS. The disease burden from HIV/AIDS spreads to encompass the entire household, with one study from the Free State province in South Africa finding that people living in a household where at least one person is infected are 3.5 times more likely to have been ill in the last month (Booysen 2002). At the same time, household gross domestic product (GDP) in AIDS-infected households is 19% lower than uninfected households, combined with the increased financial burdens for infected households for medical and funeral expenses (Lewis 2004). Other illnesses would likely have similar effects on household vulnerability, reflecting the same pathways of increased dependence. For that reason, the indicator used to represent this in the demographic structure subindex is a nominal category of whether or not a household has a member who is suffering from a long-term or recurrent illness.

1.15.6 Conclusion

This chapter has provided an overview of the linkages between climate, vulnerability, and health, with a specific focus on southern Africa. Determining the effects of climate parameters on people is dependent on their vulnerability. Initial climate impact assessments assumed that people were passive recipients of global environmental change (i.e., the top-down, outcome vulnerability), only affected insofar as climate affected ecosystems on which they depend. Critiques of this approach posited that people are not all the same, and, in addition to the nature of exposure, their social characteristics (including their health status) mediate how they will experience that exposures and whether it will translate into adverse impacts or not. Moreover, the outcome vulnerability starts with the assumption that changes in regional and local climate statistics can be skillfully predicted, which, as summarized in Preface to this book, is not always the case. A more inclusive assessment of risk can be developed using the bottom-up, contextual vulnerability approach in which the entire spectrum of future possible climates is considered.

Climate factors intersect with health in various ways. The range of many diseases is affected by temperature and rainfall patterns. This includes vector-borne malaria and waterborne cholera, as well as meningitis, Rift Valley fever, and dengue fever. However, the impacts on people again depend on their social vulnerability. At the same time, if more people have a compromised health status, they will likely have a higher social vulnerability to climate. In this way, climate, vulnerability, and health run the risk of negatively reinforcing each other, leading to worse impacts than one alone.

The adverse economic and developmental consequences of climate and disease (and broader suboptimal health status) have been recognized (e.g., Stern 2006; Gallup and Sachs 2001). At the same time, there is evidence to show that focusing resources on addressing climate threats and disease (and suboptimal health status) is beneficial for the economy (and often more cost-effective than dealing with the consequences) (Stern 2006). However, it is essential to begin addressing vulnerability reduction to both climate-related factors and disease in tandem. This is because negatively reinforcing interactions between the two can offset progress made to date. Any change in regional and local climate statistics, e.g., may cause additional risk of contracting malaria faster (through additional exposure) than the existing public health responses are able to reduce it. Increased disease burden, in turn, increases the social vulnerability of people to climate. Ultimately, climate-resilient sustainable development that addresses climate and health risks is the most appropriate way to reduce vulnerability to both risks and the intersecting vulnerabilities that result.

EDITOR-IN-CHIEF

Dr Roger A. Pielke is currently a senior research scientist in CIRES and a senior research associate at the University of Colorado-Boulder in the Department of Atmospheric and Oceanic Sciences (ATOC) at the University of Colorado in Boulder (November 2005—Present). He is also an emeritus professor of atmospheric science at Colorado State University and has a 5-year appointment (April 2007—March 2012) on the Graduate Faculty of Purdue University in West Lafayette, Indiana.

He has studied terrain-induced mesoscale systems, including the development of a three-dimensional mesoscale model of the sea breeze, for which he received the NOAA Distinguished Authorship Award for 1974. He has worked for NOAA's Experimental Meteorology Lab (1971—74), The University of Virginia (1974—81), and Colorado State University (1981—2006). He served as Colorado State Climatologist from 1999—2006. He was an adjunct faculty member in the Department of Civil and Environmental Engineering at Duke University in Durham, North Carolina (July 2003—06). He was a visiting professor in the Department of Atmospheric Sciences at the University of Arizona from October to December 2004.

He has served as chairman and member of the AMS Committee on Weather Forecasting and Analysis, and was the chief editor for the Monthly Weather Review for 5 years from 1981 to 1985. In 1977, he received the AMS Leroy Meisinger Award for ‘fundamental contributions to mesoscale meteorology through numerical modeling of the sea breeze and interaction among the mountains, oceans, boundary layer, and the free atmosphere’. He received the 1984 Abell New Faculty Research and Graduate Program Award, and also received the 1987/1988 Abell Research Faculty Award. He was declared ‘Researcher of the Year’ by the Colorado State University Research Foundation in 1993. In 2000, he received the Engineering Dean's Council Award from Colorado State University.

He authored a book published by Academic Press entitled ‘Mesoscale meteorological modeling’ in 1984 with a 2nd edition in 2002, a book for Routledge Press entitled ‘The Hurricane in 1990, a book (coauthored with W.R. Cotton) for Cambridge Press entitled ‘Human impacts on weather and climate in 1995; 2nd ed., 2006, a book (coauthored with R.A. Pielke, Jr.) entitled ‘Hurricanes: Their nature and impacts on society’ published in 1997 by John Wiley and Sons, and was co-chief editor (with R.A. Pielke, Jr.) of a book entitled ‘Storms’ published by Routledge Press in 1999.

He was elected as a fellow of the AMS in 1982 and fellow of the American Geophysical Union in 2004. From 1993—96, he served as editor-in-chief of the US National Science Report to the IUGG (1991—94) for the American Geophysical Union. From January 1996 to December 2000, he served as co-chief editor of the *Journal of Atmospheric Science*. In 1998, he received NOAA's ERL Outstanding Scientific Paper (with Conrad Ziegler and Tsengdar Lee) for a modeling study of the convective dryline. He was designated a Pennsylvania State Centennial Fellow in 1996, and named the Pennsylvania State College of Earth and Mineral Sciences Alumni of the year for 1999 (with Bill Cotton). He is currently serving on the AGU Focus Group on Natural Hazards (August 2009—Present) and the AMS Committee on Planned and Inadvertent Weather Modification (October 2009—Present). He is among one of three faculties and one of four members listed by ISI Highly Cited in Geosciences at Colorado State University and the University of Colorado at Boulder, respectively.

He has published over 370 papers in peer-reviewed journals, 55 chapters in books, coedited 9 books, and made over 700 presentations during his career to date. The listing of papers can be viewed at the project website: http://cires.colorado.edu/science/groups/pielke/pubs/. He also launched a science weblog in 2005 to discuss weather and climate issues. This weblog was named one of the 50 most popular Scienceblogs by Nature Magazine on 5 July 2006 and is located at http://pielkeclimatesci.wordpress.com/.

VOLUME EDITORS

Dr Jimmy Adegoke is an award winning climate scientist whose research focuses on understanding the relationships between changing land surface processes and diverse indicators of environmental change. His recent work focuses on societal impacts of environmental change including air pollution studies in rapidly changing midlatitude urban areas and climate impacts on water resources in the Lake Chad Basin. He teaches at the University of Missouri-Kansas City (UMKC) where he served as chair of the Department of Geosciences from 2008—10. From August 2010 until very recently, he was Executive Director of the Council for Scientific and Industrial Research (CSIR) Natural Resources and Environment (NRE) Division, Pretoria, South Africa where he also served as the Director of the Applied Center for Climate and Earth Systems Science (ACCESS), a Center of Excellence (CoE) of the South Africa Department of Science and Technology (DST) Global Change Grand Challenge (GCGC) program. He is a member of several professional societies including the American Geophysical Union (AGU), Association of American Geographers (AAG), and American Meteorological Society (AMS). He is on the advisory council of the African Association for Remote Sensing of the Environment (AARSE) and also serves on the technical advisory committee of several United Nations applied science programs, including the United Nations Educational Scientific and Cultural Organization (UNESCO) crosscutting project on the application of remote sensing for water resources and ecosystem management in Africa. He lives in Kansas city where he served a 3-year team as an appointee of the Mayor of Kansas City Missouri (KCMO) on the city's Environmental Management Commission (EMC).

Dr Caradee Y. Wright is a senior researcher at the Council for Scientific and Industrial Research in the Climate Studies, Modelling and Environmental Health Research Group, leading the environmental health research team. She holds a PhD in public health from the University of Otago and an MSocSc in geography and environmental management from the University of Natal. Her research focuses on personal solar ultraviolet radiation exposure, personal dosimetry, health risk assessment, and skin cancer prevention. Recently, she has also worked in the field of air quality and finding ways to integrate public health into air quality management. She also works in the broader field of environmental health, leading large epidemiological, cross-sectional community surveys to consider the impacts of environmental pollution on community health and appropriate interventions. She is cochair of the South African Young Academy of Science, a member of the Global Young Academy, a council member of the National Association for Clean Air, and founder of the Environmental Health Research Network. In 2012, she was named one of 200 top young South Africans for her efforts to establish a SunSmart Research Programme and Lab in South Africa.

Dr Dev Niyogi is an associate professor with joint appointment in the Departments of Agronomy and Earth, Atmospheric, and Planetary Science at Perdue University.

He is also the State Climatologist for Indiana and Director of the Indiana State Climate Office. His research seeks to advance the understanding of vegetation and land surface processes in environmental, weather forecasting, and climate analyses, using a combination of dynamical models and surface, satellite remote sensing, and multiscale analysis products.

His research deals with the understanding and representation of the effects of vegetation – land surface processes in environmental processes at different scales. He is one of the three invited, nonfederal representatives to the community modeling effort of the Weather Research and Forecast (WRF) model working group on Land Surface Models, and to the Federal Geophysical Data Commission (FGDC) Spatial Climate Working Group.

He has authored or coauthored 25 successful proposals for external grants totaling over $3M. He vertically integrates undergraduate, graduate, and postdoctoral researchers in his research and is very interdisciplinary in developing collaborative projects.

Dr George Kallos is a professor at the University of Athens, School of Physics, Division of Environmental Physics and Meteorology. He leads the Atmospheric Modeling and Weather Forecasting Group (AM & WFG). He has a BSc from the University of Athens/School of Mathematics (1975). He obtained his MSc (1983) and PhD (1985) in Geophysical Sciences/Atmospheric Sciences Division, Georgia Institute of Technology, School of Geophysical Sciences, USA. He has 110 publications in peer review scientific journals, more than 230 presentations and publications in conference proceedings publications, 10 contributions in books and more than 200 other publications in subjects related to atmospheric physics and chemistry, sea-state conditions, and renewable energy production. He has been invited 70 times to give talks in conferences, seminars, etc. His published work has received >2000 citations. He has participated in 80 projects. He has organized 12 conferences related to air pollution and dust transport in the Mediterranean. He has supervised 10 PhDs and over 100 MSc theses and participated in 20 PhD examinations in Greece and Europe. He is an associate editor for the journals: '*Environmental Fluid Mechanics*', '*Advances in Meteorology*', '*International Journal of Geosciences*', '*Atmospheric Pollution Research*', and '*Journal of Aerospace Operations*'. He was awarded the International Union of Air Pollution Prevention Association – IUAPPA award for his work on 'Long-range transport and air quality work in the Mediterranean region'. His current research activities are related to atmospheric, climatic, air pollution, and sea-state model development and forecasting. He focuses in fully coupled modeling systems. The latest model developments are related to nucleation processes in clouds, desert dust cycle and its direct and indirect effects. Research activities related to renewable energy resources (wind, ocean, solar) are focusing on high accuracy atmospheric model development, energy relationships and predictions, and protection from extremes.

Timothy Seastedt received his BA in biology from the University of Montana, an MS degree in biological sciences from the University of Alaska at Fairbanks, and a PhD degree from the University of Georgia. He was on the faculty at Kansas State University and is currently a professor of Ecology and Evolutionary Biology and fellow of INSTAAR at the University of Colorado, Boulder. Much of his research has been conducted as part of the Long-Term Ecological Research (LTER) programs at KSU and CU. His interests focus on terrestrial ecosystem ecology and the causes and consequences of biotic change. His recent activities have emphasized the ongoing changes found along the grassland to (melting) glacier gradient that exists in the Colorado Front Range.

Katharine Suding received her BA in biology from Williams College and a PhD degree from the University of Michigan. She was on the faculty at University of California Irvine and is currently a professor in Environmental Science, Policy and Management at the University of California Berkeley. Her background is in plant community and ecosystem ecology, with current interests in restoration, resilience, and environmental change.

Faisal Hossain received his PhD from the University of Connecticut in 2004. Prior to that, he had earned his MS and BS from the National University of Singapore and Indian Institute of Technology, Varanasi, respectively. He is currently an associate professor in the Department of Civil and Environmental Engineering where he received one of the highest awards of University – the Caplenor Research Award in 2012. His research interests comprise hydrologic remote sensing, uncertainty modeling of water cycle variables, human modification of extreme hydro-climatology, sustainable water resources engineering, space-borne transboundary water resources management, engineering education, and public outreach. He is also the recipient of awards such as NASA Earth System Science Fellowship (2002), Outstanding PhD Thesis Award (2005), NASA New Investigator Award (2008), American Society of Engineering Education (ASEE) Outstanding Research Award (2009), National Association of Environmental Professionals Education Excellence Award (2010), US Fulbright Faculty Award (2012), G.O.L.D. (Graduate Of the Last Decade) award from University of Connecticut (2012), and American Geophysical Union (AGU) Charles Falkenberg Award. He has published over 85 peer-reviewed journal articles, authored an undergraduate-level textbook, edited two book volumes, and contributed eight book chapters. His recent research on human modification of extreme events by artificial reservoirs has been featured by public media such as the BBC, National Geographic, New Scientist, Newsweek, Fox News, MSNBC, Wired.com, and German Public Radio. He served as an associate editor of *Journal of American Water Resources Association* from 2006–10. Currently, he serves as an associate editor for *Journal of Hydrometeorology* and a lead editor for the water volume of Elsevier Sciences five volume reference series on '*Climate Vulnerability: Understanding and Addressing Threats to Essential Resources*'.

PREFACE

We are pleased to introduce the five-volume set of books on bottom-up, resource-based vulnerability assessments of the societally and environmentally key resources of water, food, energy, human health and well-being, and ecosystem function. This inclusive bottom-up vulnerability concept requires the determination of the major threats to these resources from climate, but also from other social and environmental issues. After these threats are identified for each resource, the relative risk from natural- and human-caused climate change (estimated from global climate model (GCM) projections, as well as the historical, paleorecord, and worst case sequences of events) can be compared with other environmental and social risks in order to adopt the optimal mitigation and adaptation strategies.

The bottom-up, resource-based approach (referred to by O'Brien (2009) as 'contextual vulnerability') that is the focus of the volume is distinct from the Intergovernmental Panel on Climate Change (IPCC) top-down assessment of vulnerability based on the multidecadal GCM predictions (projections) which O'Brien defined as 'outcome vulnerability' (**Table 1** and **Figure 1**).

An excellent example of the contextual vulnerability is the paper by Romero-Lankao et al. (2012) who concluded in a study of the literature that urban vulnerability is dominated by epidemiological studies and top-down assessments, but that inherent urban vulnerability and urban resilience approaches (the contextual vulnerability) are what is required in order to illuminate a more complete set of drivers of urban vulnerability. They also showed that the large majority of papers on vulnerability use the outcome vulnerability approach. However, as discussed below, this top-down approach has major flaws.

First, there is the issue that the term 'climate' has two definitions. The broader view (and the one adopted by NRC (2005)) is that climate consists of the atmosphere, oceans, land, and cryosphere. This is the preferred usage. The second definition is that climate is the term used for the long-term (e.g., multidecadal) statistics of weather.

As reported in the NRC (2005) report and written in the Pielke et al. (2009) article with respect to human climate forcings.

> In addition to greenhouse gas emissions, other first-order human climate forcings are important to understanding the future behavior of Earth's climate. These forcings are spatially heterogeneous and include the effect of aerosols on clouds and associated precipitation [e.g., Rosenfeld et al. 2008], the influence of aerosol deposition (e.g., black carbon (soot) [Flanner et al. 2007] and reactive nitrogen [Galloway et al. 2004]), and the role of changes in land use/land cover [e.g., Takata et al. 2009]. Among their effects is their role in altering atmospheric and ocean circulation features away from what they would be in the natural climate system [NRC 2005]. As with CO_2, the lengths of time that they affect the climate are estimated to be on multidecadal timescales and longer.

and

> "…the natural causes of climate variations and changes are important, as are the human influences. The human climate forcings involve a diverse range of first-order climate forcings, including, but not limited to, the human input of carbon dioxide (CO2). Most, if not all, of these human influences on regional and global climate will continue to be of concern during the coming decades."

Threats from climate involve any one or combination of climate variables as illustrated in **Figure 2**. There do not, of course, have to be changes in the statistics of these variables to constitute a risk. The term

Table 1 Contrast between a top-down versus bottom-up assessment of the vulnerability of resources to climate variability and change

Approach	*Comparative vulnerability*	*Contextual vulnerability*
Assumed dominant stress	Climate, recent greenhouse gas emissions to the atmosphere, ocean temperatures, aerosols, etc.	Multiple stresses: climate (historical climate variability, land use and water use, altered disturbance regimes, invasive species, contaminants/pollutants, habitat loss, etc.)
Usual timeframe of concern	Long-term, doubled CO_2 30—100 years in the future.	Short-term (0—30 years) and long-term research.
Usual scale of concern	Global, sometimes regional. Local scale needs downscaling techniques. However, there is little evidence to suggest that present models provide realistic, accurate, or precise climate scenarios at local or regional scales.	Local, regional, national, and global scales.
Major parameters of concern	Spatially averaged changes in mean temperatures and precipitation in fairly large grid cells with some regional scenarios for drought.	Potential extreme values in multiple parameters (temperature, precipitations, frost-free days) and additional focus on extreme events (floods, fires, droughts, etc.) measures of uncertainty.
Major limitations for developing coping strategies	Focus on single stress limits preparedness for other stresses. Results often show gradual ramping of climate change-limiting preparedness for extreme events. Results represent only a limited subset of all likely future outcomes — usually unidirectional trends. Results are accepted by many scientists, the media, and the public as actual ‘predictions’. Lost in the translation of results is that all models of the distant future have unstated (presently unknowable) levels of certainty or probability.	Approach requires detailed data on multiple stresses and their interactions at local, regional, national, and global scales, and many areas lack adequate information. Emphasis on short-term issues may limit preparedness for abrupt “threshold” changes in climate sometime in the short or long term. Requires preparedness for a far greater variation of possible futures, including abrupt changes in any direction — this is probably more realistic, yet difficult.

Adapted from Kabat et al. 2004.

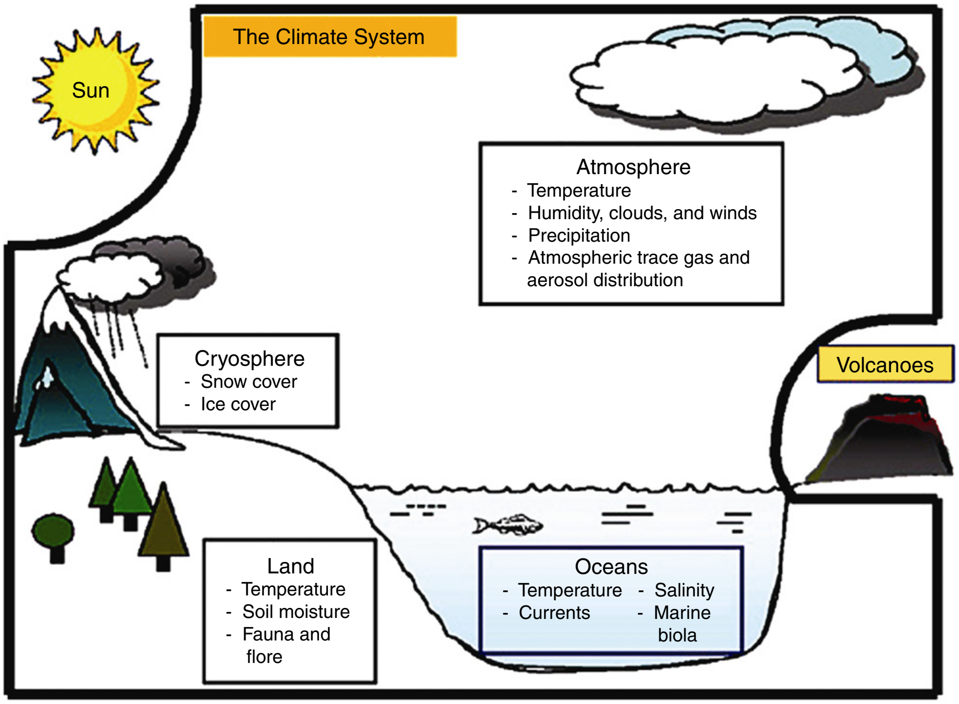
Figure 1 Framework depicting two interpretations of vulnerability to climate change: (a) outcome vulnerability and (b) contextual vulnerability. *From: Füssel (2009) and O’Brien et al. (2007).*

‘climate change’ should be used to describe any multidecadal or longer alteration in one or more physical, chemical, and/or biological components of the climate system, but as explained below, this terminology has morphed into multiple, diverse (and often mutually exclusive) definitions as used by the impacts communities.



The Climate System
Sun
Atmosphere
- Temperature
- Humidity, clouds, and winds
- Precipitation
- Atmospheric trace gas and aerosol distribution
Cryosphere
- Snow cover
- Ice cover
Volcanoes
Land
- Temperature
- Soil moisture
- Fauna and flore
Oceans
- Temperature
- Currents
- Salinity
- Marine biola

Figure 2 The climate system, consisting of the atmosphere, oceans, land, and cryosphere. Important state variables for each sphere of the climate system are listed in the boxes. For the purposes of this report, the Sun, volcanic emissions, and human-caused emissions of greenhouse gases and changes to the land surface are considered external to the climate system (NRC 2005).

First, climate is never static (Lovejoy and Schertzer 2012). As written in Rial et al. (2004)

> "The Earth's climate system is highly nonlinear: inputs and outputs are not proportional, change is often episodic and abrupt, rather than slow and gradual, and multiple equilibria are the norm."

The assumption of a stable climate system (e.g., the reason for the use of the terminology 'climate stabilization') in the absence of human intervention is a mischaracterization of the behavior of the real climate system. Humans are now adding to the complexity of forcings and feedbacks, but change has always been a part of the climate system. 'Climate change' is, and always has, been occurring. The added word 'change' is, therefore, redundant.

Moreover, there are additional misunderstandings. 'Global warming', which is an increase in the global annual average heat content measured in Joules, is often incorrectly equated to mean 'climate change'. Global warming, however, is just a subset of "climate change."

The term 'climate change', is also being erroneously used to mean only 'anthropogenic caused changes in climate' from nearly 'static' climatic conditions. Frequently, just the human input of greenhouse gases is assumed to be the reason for 'climate change'. For example, NRC (2010) (Climate Stabilization Targets: Emissions, Concentrations, and Impacts Over Decades to Millennia (2010)) states

> "This new report from the National Research Council concludes that emissions of carbon dioxide from the burning of fossil fuels have ushered in a new epoch where human activities will largely determine the evolution of Earth's climate."

Thus, the recommendations to the authors of the volume (not always accepted) were to replace terminology, such as climate change, climate stabilization, and climate disruption, with accurate terminology. When changes in climatic conditions are discussed, it was requested that the actual climate variables (such as temperature, precipitation, length of growing season) that are being altered, be specified. Phrases such as 'changes in regional and global climate statistics' could also be used.

There is a very fundamental reason to limit the use of 'climate change' by the impacts community. Key societal and environmental resources, such as water, food, energy, ecosystem function, and human health respond to climate, not just to an incremental change in the climatic conditions. As noted earlier, the assumption of a stable climate system, in the absence of human intervention, is a mischaracterization of the behavior of the real climate system.

However, some authors retained the use of the terminology 'climate change'. It was acquiesced as long as there was a significant contribution in their chapter to a broad-based assessment of risk to the key resource they were discussing.

Another misused term is 'global change', when really what is almost always meant is a local and/or regional change in the environmental conditions, including from climate. The accurate terminology should be 'environmental change'. The term 'environmental change' is, therefore, preferred rather than 'global change', as the latter terminology is very much a top-down viewpoint. Almost all impacts on key resources are on the local and regional scale.

We also requested the authors start with the risks and factor in the climate threats after thresholds, etc. were first obtained. This was not done in some chapters, but this information can still be extracted from the text. Obtaining the spectrum of risks first is the more inclusive way to assess threats to key resources, and thus, in the view, to prepare the optimal mitigation and adaptation strategies.

For the climate component of risk, the outcome vulnerability (the top-down) approach relies on skillful weather predictions and analyzes with a regional and a local focus. For weather prediction on time periods of days to a week or two, excellent skillful predictions are available for use in outcome vulnerability assessments. On seasonal timescales, there is also some limited predictive skill to apply to outcome vulnerability assessments, particularly for such well-defined weather events such as an El Niño or La Niña (Castro et al. 2007). However, for decadal and multidecadal predictions little, if any, predictive skill has been shown in hindcast climate model predictions of changes in regional weather statistics beyond what is available to the impacts community via the historical, recent paleorecord and a worst case sequence of weather events.

To illustrate the lack of skill, the conclusions from several papers have been summarized. Fyfe et al. (2011) concluded that

> "….for longer term decadal hindcasts a linear trend correction may be required if the model does not reproduce long-term trends. For this reason, we correct for systematic long-term trend biases."

Xu and Yang (2012) find that without tuning from real world observations, the model predictions are in significant error. For example, they found that

> …the traditional dynamic downscaling (TDD) [i.e. without tuning) overestimates precipitation by 0.5-1.5 mm d-1…..The 2-year return level of summer daily maximum temperature simulated by the TDD is underestimated by 2-6°C over the central United States-Canada region."

The paper van Oldenborgh et al. (2012) report just limited predictive skill in two regions of the oceans on the decadal time period, but no regional skill elsewhere, when they conclude that:

> "A 4-model 12-member ensemble of 10-yr hindcasts has been analysed for skill in SST, 2m temperature and precipitation. The main source of skill in temperature is the trend, which is primarily forced by greenhouse gases and aerosols. This trend contributes almost everywhere to the skill. Variation in the global mean temperature around the trend does not have any skill beyond the first year. However, regionally there appears to be skill beyond the trend in the two areas of well-known low-frequency variability: SST in parts of the North Atlantic and Pacific Oceans is predicted better than persistence. A comparison with the CMIP3 ensemble shows that the skill in the northern North Atlantic and eastern Pacific is most likely due to the initialisation, whereas the skill in the subtropical North Atlantic and western North Pacific are probably due to the forcing."

Anagnostopoulos et al. (2010) report that

> "…. local projections do not correlate well with observed measurements. Furthermore, we found that the correlation at a large spatial scale, i.e. the contiguous USA, is worse than [even] at the local scale."

Stephens et al. (2010) wrote

> "models produce precipitation approximately twice as often as that observed and make rainfall far too lightly…..The differences in the character of model precipitation are systemic and have a number of important implications for modeling the coupled Earth system …….little skill in precipitation [is] calculated at individual grid points, and thus applications involving downscaling of grid point precipitation to yet even finer-scale resolution has little foundation and relevance to the real Earth system."

van Haren et al. (2012) concluded from their study with respect to climate model predictions of precipitation that

> "An investigation of precipitation trends in two multi-model ensembles including both global and regional climate models shows that these models fail to reproduce the observed trends….. A quantitative understanding of the causes of these trends is needed so that climate model based projections of future climate can be corrected for these precipitation trend biases…. To conclude, modeled atmospheric circulation and SST trends over the past century are significantly different from the observed ones."

Sun et al. (2012) found that

> "…in global climate models, [t]he radiation sampling error due to infrequent radiation calculations is investigated …….. It is found that…. errors are very large, exceeding 800 W m^{-2} at many non-radiation time steps due to ignoring the effects of clouds…."

There is an important summary of the limitations in multidecadal regional climate predictions in Kundzewicz and Stakhiv (2010) who succinctly conclude that

> "Simply put, the current suite of climate models were not developed to provide the level of accuracy required for adaptation-type analysis."

Since the top-down outcome vulnerability approach depends on skillful decadal and longer regional and local climate predictions, yet they have shown little if any skill, another approach is needed.

For this reason, the volume set of five books presents an alternate approach – the bottom-up, resource-based outcome (contextual) vulnerability perspective. The goal of the set was to focus on the climate component of stress but also consider, in-depth, other environmental and social threats.

The text of the articles is written at a level that allows undergraduate students to understand the material, while providing active researchers with a ready reference resource for information in the respective field.

The questions requested to the authors address with respect to a specific resource were:

1. Why is this resource important? How is it used? To what stakeholders is it valuable?
2. What are the key environmental and social variables that influence this resource?
3. What is the sensitivity of this resource to changes in each of these key variables? This includes, but is not limited to, the sensitivity of the resource to climate variations and change on short (e.g., days), medium (e.g., seasons), and long (e.g., multidecadal) timescales.
4. What changes (thresholds) in these key variables would have to occur to result in a negative (or positive) response to this resource?
5. What are the best estimates of the probabilities for these changes to occur? What tools are available to quantify the effect of these changes? Can these estimates be skillfully predicted?
6. What actions (adaptation/mitigation) can be undertaken in order to minimize or eliminate the negative consequences of these changes (or to optimize a positive response)?
7. What are specific recommendations for policymakers and other stakeholders?

There are also overview chapters that discuss the science of the resource.

Several authors insisted on focusing on the use of the outcome vulnerability (top-down) approach based on the multidecadal GCM projections (statistically or dynamically downscaled) as the starting point of their chapters. The chapters were accepted, despite this shortcoming, because when they finally discussed adaptation in their text, they did present the broader-based bottom-up focus that is the centerpiece of the volume. Readers,

however, need to be aware that the top-down, GCM scenarios are only a subset, at best, of what is plausible in the coming decades. Multidecadal predictions of changes in regional and local climate statistics have not shown skill when run in a hindcast mode for the past several decades.

In summary, the goal of the five-volume set of books is to document the value of a bottom-up, resource-based assessment of risk to key resources, as illustrated schematically in Figure 3a—e. Most, but not all, authors accepted this framework. This can be assessed without having any predictability on

multidecadal time periods. It is an alternative (and more inclusive) perspective than the IPCC top-down outcome vulnerability approach which starts with the GCMs as the overarching framework. In the bottom-up approach, the scenarios from the GCM predictions should only enter after the specific threats to the resources are determined and even then, they provide, at best, a limited set of insights into what is possible.

Preface - Vulnerability of Food Resources to Climate

D Niyogi, Department of Agronomy, and Department of Earth and Atmospheric Sciences, Purdue University, West Lafayette, IN, USA

© 2013 Elsevier Inc. All rights reserved.

Agriculture as an enterprise is at a crossroads of increasing productivity and demand. Food security continues to be one of the top problems facing the growing world population. The issue is becoming critical as crop yields and animal productivity rates are flattening or decreasing in some cases and the demand for agricultural product continues to increase. A number of assessments have shown that technology, regional practices, and regional climate hold the key for enhancing and sustaining agricultural productivity. The interplay between agriculture and climate has been well known since prehistoric times. Throughout the rise of civilization, locales and climates suitable for agriculture have been highly coveted and became seats of economic development. At present, there are several breadbasket regions, such as the US Corn Belt, that carry the bulk of global production demands. Additionally, there are pockets of areas throughout the world with intense animal agriculture activities dominating the food source for a world with growing economic capabilities.

Agricultural commodities, from crops to animals to fruits and vegetables to fisheries are currently at a delicate juncture balancing productivity demands, sustainability, regulations, and climatic vagaries. Regional and global climatic patterns have always had significant shifts in terms of the timing, magnitude, intensity, and rates of meteorological events such as precipitation or high temperature events even in the natural system (Rial et al. 2004; Lovejoy and Schertzer 2012). With increasing human influence on the climatic system (NRC 2005), the corresponding need to assess potential effects on future food security has become urgent.

The traditional way of studying agriculture–climate interactions involves a so-called 'top-down' approach in which different current and future scenarios of regional meteorology are prescribed as input to a crop model and corresponding yield changes are obtained. These changes are then used for providing guidance regarding the potential climate impact on the regional agricultural potential yield and productivity. This approach has been used effectively in many studies and has been integrated with economic and impact assessment studies.

In reality, however, a region's agricultural productivity depends on a number of factors – both climatic and nonclimatic – that can change from one region to another. For example, agricultural productivity can be intimately tied to the region's water availability. In this case, if climate patterns indicate a reduction in rainfall, it is highly likely that corresponding top-down crop model estimates will show a reduction in crop yields. In the real world, a number of factors – such as crop planting dates, crop variety, occurrence of extreme weather events such as late season frost or hail, agricultural subsidies for water irrigation and power, scheduling of farm activities, and regional policies such as subsidies – also can play a first-order role in determining if agricultural yields will increase or decrease. Such a bottom-up, or vulnerability, approach is the focus of this book.

The ensuing chapters look at a cross-section of agricultural entities such as corn and poultry production in regions such as the US Corn Belt and present expert opinions on the various vulnerabilities that may affect agricultural productivity and food security. These chapters seek to provide a perspective and approach for conducting such vulnerability assessments where the climatic component is indeed one of the first-order influences; however, equally important are the identification and discussion of nonclimatic stresses on agricultural enterprise.

These chapters provide a cross-section and are only an exemplar of the different regions and approaches one can use in conducting these studies using the vulnerability approach. They also provide a glimpse of the complex problem that is emerging and the corresponding solutions that can be taken to understand and maintain food security.

> Cause and effect, means and ends, seed and fruit cannot be severed; for the effect already blooms in the cause, the end preexists in the means, the fruit in the seed.
>
> Ralph Waldo Emerson

2.01.1 Introduction

We stood on the edges of a small winter-wheat field in a highly productive, irrigated area of a developing country. Crop stands were poor, water was limited, and seeding date was late – because it followed late-sown grain sorghum; the farmer expected lower yields for all of those reasons. Three weeks to a month remained before harvest. Many of the nearby fields – along with this one – had numerous wheat varieties seeded in them as evidenced by wildly variable plant height. To cut costs, farmers saved their own seed sacrificing purity and quality and probably yield. Some oat heads even swayed above the wheat canopy mocking the purist in people like me. The farmer when asked his major problems with wheat production, promptly mentioned, or perhaps it was the translator, water, late planting, and climate change – the latter resulting in longer summers, shorter winters. You would think of all the obvious management issues encountered by a farmer in a developing country like this, changes in local and regional climatic conditions would be the least and last of his concern! His focus would revolve around things he could manage: seed purity and quality, weed control, tillage, and so on. But not climate change!

This man recognized the negative impacts of climate. He understood something that most farmers – everywhere in the world – understand well. Crop production hangs on multiple interacting factors and variables a few of which they can control, but most of which they cannot. For this man, the foremost uncontrollable factor was climate. Although certainly a real and perhaps valid concern for farmers like this, a focus on controllable factors of management would produce more fruit.

Although US Corn Belt yields often exceed those of developing countries by 10 times or more, the basic controllable and uncontrollable factors are similar. The 30-year trend line for US corn yields increases at about 2 bu acre^{-1} year^{-1} (125 kg ha^{-1} year^{-1}) (Figure 1). Given that, the 2011 US trend-line yield is 159 bu acre^{-1} (9.98 MG ha^{-1}). Iowa's 2011 trend-line yield is about 177 bu acre^{-1} (11.1 MG ha^{-1}) with a 2.5 bu acre^{-1} increase per year (157 kg ha^{-1} year^{-1}) (USDA-NASS).

The central proposition of this chapter is that genetics, management, and climate have interacted to dramatically improve corn yields over time. The three factors are interrelated, confounded as the flower, fruit, and seed.

In this chapter, I would like to address these questions:

1. What advances contributed to the dramatic US corn yield increases?
2. Where is corn vulnerable relative to climate?

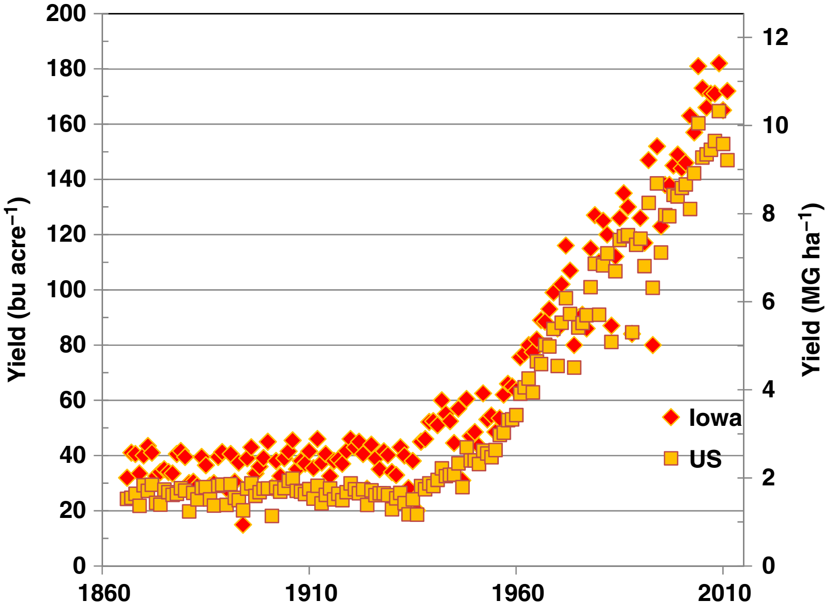

Figure 1 Iowa and US corn yields, 1866–11. Source: Adapted from USDA-NASS, 2011: Crop Production 2010 Summary, http://usda01.library.cornell.edu/usda/current/CropProdSu/CropProdSu-01-12-2011_new_format.pdf.

3. What opportunities – and concerns – exist for corn in the decades to come?

Unless we know where we have come from, we will not know where we are going or, for that matter, how to get there. For this reason, let us examine factors that affected corn production systems over time. This will better enable us to respond well to future needs for change.

2.01.2 Advances in Corn Production in the US Corn Belt

> Throughout history, farmers have adopted new crop varieties and adjusted their practices in accordance with changes in the environment.
>
> (CSSA 2011)

My great grandfather A. G. Mayne farmed at the turn of the twentieth century in north central Illinois. If he were alive today, he would hardly recognize a modern corn field let alone the seeds, hybrids, fertilizers, herbicides, equipment, and other inputs that have collectively allowed the huge increases in productivity displayed in Figure 1. The changes border on dramatic resulting in more than a fivefold increase in corn yields.

Corn is the most widely grown crop in the United States. Iowa sits in the middle of the US Corn Belt and often has more corn acres than any other state with area ranging between 13 and 14 × 10^6 acres (5.3–5.7 × 10^6 ha) (USDA-NASS 2011) per year. Good soils, capable farmers, a viable public research and extension system, and excellent agribusiness resources position Iowa well. A great place to grow corn! Thus, Iowa will serve as a 'case study' along with examples and information from a few other states to address the first question listed above:

> What advances contributed to the dramatic US corn yield increases?

2.01.2.1 Genetics

It never fails; the answer is always the same. When I display charts like Figure 1 to farmer audiences in Extension meetings across Iowa, I ask the question, "So what happened in the 1940s that triggered the rapid increase in corn yields?" After nearly 80 years of yield in Iowa ranging between 30 and 40 bu acre^{-1} (1.88–2.51 MG ha^{-1}), yields abruptly began climbing at about a bushel per acre per year. What happened then? The first response is usually, 'Hybrids!' Indeed that is partly correct, but certainly not independent of other factors. Duvick (2005) attributes about 50% of the increase in corn yields to management and about 50% to breeding. Hybrids without associated improvements in other inputs and practices proved unproductive. With that in mind, let us first look at the dynamic changes in corn genetics over the last nearly century and a half.

2.01.2.1.1 Open-Pollinated Varieties

The ear measures at least 10 inches (25 cm) long and tapers from about 2.5 inches in diameter (6.4 cm) at its base to 2 inches (5 cm) at the tip that gently rounds off, like an Iowa silo. Twenty rows of well-dented kernels with slightly wrinkled tops encircle the dark red cob, each row 54 kernels long. Perhaps it originally held more than a thousand well-shaped large kernels in near-perfect alignment, tightly stacked side-by-side, row-by-row. Some kernels fell off over the years, decades, the last century, actually over the last 105 years. A modern hybrid might contain half that many kernels. Is this an extraordinary ear, yes. A prize winning ear, yes!, the 'Pascal Ear.'

D. L. Pascal of DeWitt, Iowa, entered the ear of Reid's Yellow Dent in the state's grain show, in 1907, the show's best ear. Later the ear was declared "Champion of the America" at the National Corn Show. In contrast to standard practice for the time, not a single kernel from it served for breeding purposes.

In 1908, M. L. Bowman and B. W. Crossley, both Iowa State College (now Iowa State University, ISU) professors, printed a photo of Pascal's ear beside an ear of pod corn as the first figure in their 549 page book titled, *Corn, growing, judging, breeding, feeding, and marketing.* Later, someone mounted the ear vertically on a long screw and placed it in a glass trophy case framed nicely in walnut. At some point, Mrs Pascal presented the ear to ISU where it reportedly remained in the office of the Professor of Farm Crops. I spotted it early last year near the ceiling in an ISU Agronomy Hall office on an almost empty bookshelf, dusty and forgotten – with a note explaining some of what I have mentioned here.

Ears of modern hybrids look like dwarfs in comparison (**Figure 2**). What did farmers and corn breeders believe about the relationship between ear size and yields in 1907? Can you imagine my great grandfather Mayne and his neighbors in north central Illinois hearing about it and perhaps even seeing its picture in Bowman and Crossley's book as they toiled to extract 30 to 40 bu acre^{-1} (1.88–2.51 MG ha^{-1}) with well-bred horses and their home-grown seed corn? Other Corn Belt farmers undoubtedly dreamed of it too. The more math-oriented among them might have thought, "If each of the three seeds check planted into the over 3500 hills per acre (about 8600 per ha) in 42-inch rows (1.06 m) produced an ear like that … just imagine!"

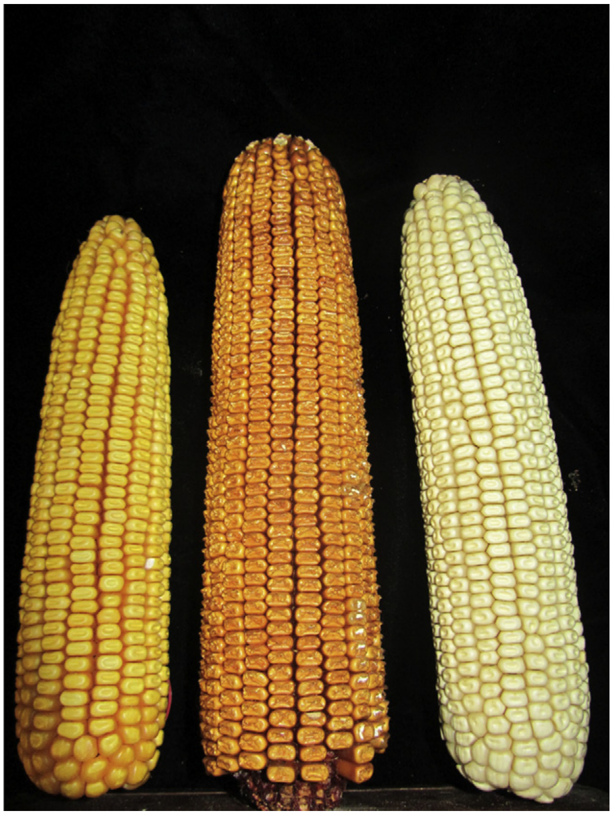

Figure 2 Pascal ear, 1907, center, and modern counterparts.

Seeding rates have astronomically increased since 1907. The Iowa average now hovers right at 30 000 plants acre^{-1} (74.1×10^3 ha^{-1}) and increases about 400 plants acre^{-1} year^{-1} (1000 plants ha^{-1}) (USDA-NASS 2011). A modern field with ears like the one on the left in **Figure 2** might produce 200 bu acre^{-1} (12.6 MG ha^{-1}). The white corn ear on the right in **Figure 2** – from one of our nation's current yield champions – might yield 330 bu acre^{-1} (20.7 MG ha^{-1}) if planted at 35 000 or more seeds per acre (86 400 ha^{-1}). A field with ears like Pascal's ear planted at about 11 000 seeds acre^{-1} might yield 130 bu acre^{-1}, a fabulous yield for 1907 yet far below today's average.

Bowman and Crossley in 1908 wrote that the standard seeding rate was 2–2.5 seeds per hill for 'breeders' growing corn for 'show purposes,' with final stands of 7000–9000 plants acre^{-1} (17.2–22.2 $\times$ 10^3 plants ha^{-1}). Typical farmers then planted three to five seeds per hill. People growing for the corn shows knew then that fewer plants per acre meant bigger ears. Bigger ears, though, do not mean bigger yields.

Henry A. Wallace, as he tried to convince skeptical farmers to grow hybrid corn instead of open-pollinated corn, used to say in reference to corn ear contests, "What do looks mean to a hog?" Wallace thought of corn ear contests as beauty contests which did not represent or – in fact – promote the true genetic yield potential of corn.

One of the foremost reasons corn yields in Iowa and across the United States did not increase until the mid-1940s is that my great grandpa Mayne as well as other farmers and breeders chose seed corn based on ear size and appearance, not yield per acre. Indeed, farmers followed the recommended practice of the day. Corn is cross-pollinated; they initially neither recognized the problems associated with this fact nor the potentials! Sprague (1942) summarized corn breeding progress by saying that earlier methods of corn breeding, for example, mass selection, ear to row selection, and varietal hybridization, were "unsuccessful because of inadequate control of parentage." Parentage in open-pollinated varieties can vary from ear-to-ear and from kernel-to-kernel.

2.01.2.1.2 Hybrids

Interestingly, 2 years before the Pascal ear gained national fame, G. H. Shull, working at Cold Spring Harbor, New York, and E. M. East, first working at the Illinois Agricultural College and later at the Connecticut Experiment Station, first experimented with hybridization as a way to improve corn (Crabb 1947; Jenkins 1936). These scientists first discussed their findings in 1908. Farmers, however, continued to grow corn and select the best ears like their fathers before them. Authors like Bowman and Crossley (1908) devoted 13 pages of their book on how to select and store ears and reinforced this practice summarizing data from 39 experiments by stating, "By all means do not omit picking seed corn this fall with the idea that in the spring you will purchase entirely new seed and start in the business right … There is no corn so adapted to a given

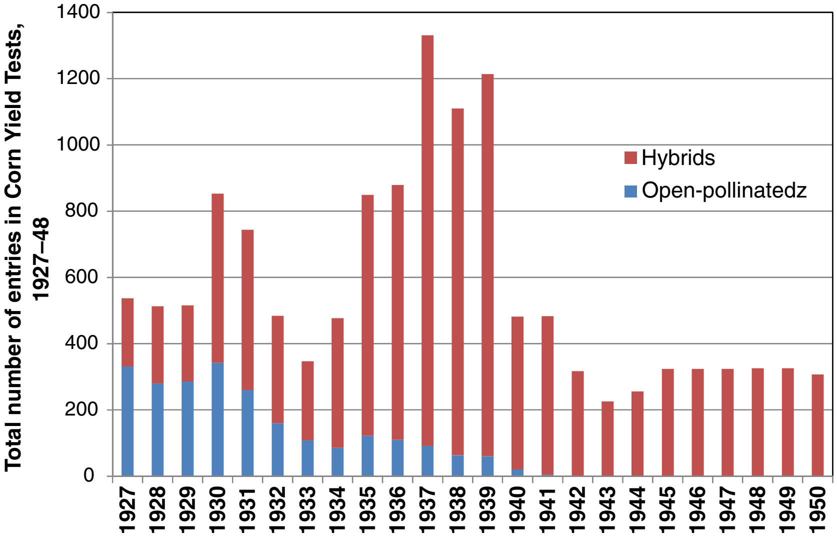

Figure 3 Open-pollinated and hybrid entries in Iowa corn yield tests, 1927–50.

locality as corn which has been successfully grown in that locality for a period of years." They had no doubts, home-grown seed was the 'surest.'

And that indeed was true for a time. Hybrid research began in earnest after Shull and East introduced the idea. In 1913, H. A. Wallace became the first private breeder to use inbreds but did not "… go at it systematically until 1919" (Jenkins 1936). The first hybrids – single crosses – performed poorly relative to open-pollinated varieties. In 1916, D. F. Jones, Connecticut Experiment Station, speculated that crossing two single-cross hybrids could result in more productive double-cross hybrids (Crabb 1947; Jenkins 1936). The innovation of double-cross hybrids changed perceptions on hybrids.

The Iowa Corn Yield Tests conducted across Iowa in the 1920s and 30s (Iowa Corn Yield Tests 1927–2011) were in part responsible for the rapid adoption of hybrids and serves as a proxy for hybrid adoption by farmers. Jenkins (1936) referred to these tests as offering the most extended comparisons of hybrid and variety yields. Hybrids yielded 9.8% more than varieties between 1926 and 1934. The largest yield increase occurred in 1934, 15.2%, which clearly indicated to farmers as well as agronomists that hybrids withstood "abnormally dry conditions of that season better than varieties" (Jenkins 1936). In Nebraska, Stewart et al. (1933) summarized 1927–32 yield contest data by stating that hybrids on average yielded 9% more than varieties and that the five best hybrids out-yielded the five best varieties by 18%.

In 1927, 62% of the entries in the Iowa Corn Yield Tests were open-pollinated varieties; the rest were commercial or experimental hybrids (Figure 3). Six years later in 1933, only 31% of the entries in the trials were open pollinated. By 1942, there were no open-pollinated varieties in the State Yield Tests. Bryan and Jugenheimer reported in 1937 that demand exceeded supply for some high-yielding hybrids. Open-pollinated varieties or inferior hybrids were thus offered as high-yielding hybrids by deceitful salesmen. Ryan and Gross (1950), in a classic sociological study of two Iowa communities, reported that during slightly more than one decade, 1927–41, all farmers in those two communities adopted hybrid corn. According to their report, hybrid corn unlike other innovations, met no organized resistance. However, there were some misgivings. Although hybrids did not affect livestock acceptance, kernels were harder than open-pollinated varieties – it was too 'flinty' – and rumors circulated – but were dispelled – that hybrids were hard on the soil. Farmers were not used to the smaller and less symmetrical ears and smaller kernels of hybrids. Traditional standards for evaluating good corn were challenged.

By 1945, nearly all entries in the Iowa Corn Yield Test (Figure 3) and 99% of Iowa's hybrids were double-cross hybrids; by 1950, 99% of hybrids grown in the United States were double-cross hybrids (Troyer 2004). However, as we initially transitioned from open-pollinated varieties to double-cross hybrids, average yields did not budge much if any at all! Iowa yields hovered around 40 bu acre^{-1} (2.5 MG ha^{-1}) from 1866 until 1942. But something happened around 1942; state average yields rose above 60 bu acre^{-1} (3.8 MG ha^{-1}) for the first time. The trend has not stopped in Iowa: 120 bu acre^{-1} in 1979 (7.53 MG ha^{-1}); 181 bu acre^{-1} in 2004 (11.35 MG ha^{-1}), and 182 bu acre^{-1} in 2009 (11.41 MG ha^{-1}).

Before 1960, double-cross corn hybrids dominated in the Corn Belt (Aldrich et al. 1975). But, in a period of 5 years, double-cross corn hybrids gave way to single-cross hybrids because single crosses were more uniform in plant and ear height and usually higher yielding (Aldrich et al. 1975). One of the first up-right leaved, single-cross hybrids, B73 × MO17 first commercially grown in 1974, proved a land-mark innovation in hybrid history and at its peak may have been accounted for 7–10% of corn grown in the United States (Troyer 2004).

Kiesselbach (1950) summarized his thinking about yield improvements at that time. Regarding hybrids he stated, "… there is no question about their great advantage over antiquated open-pollinated varieties. They have more 'oomph,' better vegetative characteristics, and higher yield." But then he conditioned this by saying, "The best corn hybrids of today with their added productivity of 15–20% owe their high yield in large measure to greater nutritional efficiency, and to disease and insect resistance or tolerance" (p. 29). Little research then supported the need for timelier planting, increased seeding rates, or narrower row spacings.

2.01.2.1.3 Transgenic Hybrids

Transgenic hybrids – hybrids genetically modified with genetic material from other species – first came on the scene in 1995 with the introduction of hybrids with European Corn Borer (*Ostrinia nubilalis*), European corn borer (ECB), resistance. These hybrids had a gene from *Bacillus thuringiensis* (Bt) which encodes a protein toxic to ECB. Later, herbicide resistant and corn rootworm resistant (RW) (*Diabrotica barberi*) hybrids were introduced. In 2011, about two- thirds of US corn contained transgenic traits for either insect resistance or herbicide tolerance or both; Iowa's (USDA-NASS 2011).

But let us be careful in the way we think about transgenic hybrids. Collectively, transgenic hybrids protect yield potential, they do not increase yield potential. They defend against insects and herbicide damage. In other words, in the absence pressure from either insects or weeds, hybrids with and without transgenic protection will perform the same.

Transgenic hybrids have not yet affected yield trends. They were grown on roughly 1/3 of US corn area by 2001. If we use that as a transition point for transgenic hybrid adoption, average US yields since then – from 2001 to 2010 – increased 2.49 bu acre^{-1} year^{-1} (156 kg ha^{-1} year^{-1}) very similar to the previous 10-year period – from 1991 to 2000 – when transgenics were a minor part of our corn production systems where yields increased 2.53 bu acre^{-1} year^{-1} (159 kg ha^{-1} year^{-1}) (USDA-NASS 2011; **Figure 1**). Transgenic hybrid adoption does not appear to have affected yield trends to date. It appears – at least based on these 10-year trends – that prior to transgenic hybrids, farmers were able to limit yield losses to ECB and RW insects and weed competition using a combination of cultural and chemical control options. But be cautious of short-term trends; they are dramatically affected by extremes.

2.01.2.1.4 Hybrid Trait Changes with Breeding Efforts

Hybrid yields have obviously changed since their introduction and mass production; so have various traits or characteristics of the hybrids. Some of these changes have been intentional, other unintentional changes occurred while breeders focused on yield. Some have improved yield and/or stress tolerance, others have had no effect. Duvick (2005) discussed these based on Pioneer hybrids released in different decades of the twentieth century and grown in the same modern environment. **Table 1** lists some of these changes.

Two of the items in **Table 1** deserve a bit of attention here. First, shortening the pollen shed, silk interval is largely responsible for increased stress tolerance of modern hybrids. In scientific papers, this is referred to as ASI, Anthesis – Silk Interval. In modern hybrids it is not uncommon to have silking occurring before pollen shed (Abendroth et al. 2011). A shorter ASI means there is less likelihood of complete pollen shed occurring before silk emergence. Stress has either little effect or may hasten pollen shed timing, but stress delays silk emergence. This shorter ASI insures better 'nick' of pollen shed and silk, reducing barren plants, and increasing kernel set and, thus, grain yield under stress.

Second, the fact that yield potential per plant has not changed over time is significant. Modern hybrids are more stress tolerant than older hybrids as just discussed. Today, one of the major stressors of any given plant is increased plant densities. Modern hybrids are far more able than older hybrids to increase yield per acre because they maintain productivity on a per plant basis in the face of increased stress agents such as increased plant densities (Duvick 2005).

Some have noted that changes in performance resulted with the introduction of single-cross hybrids. According to Troyer (2004), increases in US corn yields during the double-cross era from the 1930s to the 1960s averaged 1.01 bu acre^{-1} year^{-1} (63.3 kg ha^{-1} year^{-1}); he contrasted with trends after the introduction of single-cross hybrids after 1960. From 1960 to 2002, yields increased 1.76 bu acre^{-1} year^{-1} (110.4 kg ha^{-1} year^{-1}). However, these numbers may provide too much initial credit to the early double-cross hybrids. Yields in the 1940s, when the initial double-cross hybrids were grown, increased only 0.89 bu acre^{-1} year^{-1} (55.6 kg ha^{-1} year^{-1}) while those of the 1950s, before single-cross hybrids were introduced, increased 1.85 bu acre^{-1} year^{-1}

Table 1 Hybrid trait changes since the early twentieth century and their impacts on productivity or stress tolerance

Traits that improved grain production efficiency	*'Direction' of changes*	*Unintended stable traits*
Leaf angle	Increased (more upright)	Leaf number
Tassel size	Reduced	Leaf area index
Grain – fill period	Longer	Ears per plant
Grain dry-down rate	Faster	Yield potential per plant
Kernel weights	Increased	
Grain protein	Reduced	
Grain starch	Increased	
Traits that increase stress tolerance and yield	*Direction of changes*	
Tolerance of higher plant densities	Increased yield with higher plant densities	
Leaf rolling with drought	Increases with drought stress	
Pollen shed – silk interval	Shortened	
Barrenness	Increased resistance	
Harvest index	Greater	
Stalk and root lodging	Improved resistance	

Adapted from Duvick, D. N., 2005: The contribution of breeding to yield advances in maize. *Adv. Agron.*, **86**:83–145.

(116 kg ha^{-1} year^{-1} (**Figure 1**)) – very similar to the 1960 to 2010 single-cross hybrid era, 1.89 bu acre^{-1} year^{-1} (118.5 kg ha^{-1} year^{-1}). So although yields during the single-cross hybrid era improved yield trends and yields relative to earlier eras, yield trends for double crosses during the 1950s and those of the single crosses since then are similar.

In addition to these changes in trend lines as we transitioned from double-cross hybrids to single-cross hybrids, double-cross and single-cross hybrids may differ in their responses to environments. According to Troyer (2004), "… it is assumed that single crosses may show greater variation and standard deviations for grain yield across environments than three-way or double crosses. Single cross hybrids are genetically and phenotypically uniform … single crosses can be [generally] susceptible to pests or abiotic factors." Thus, the reduced year-to-year variation in corn yields in the 1950s may be the result of having double-crosses as the predominant hybrid type grown rather than other management or climate-related factors.

No doubt, hybrids substantially improved yields and yield potential. Yet, as Duvick (2005) suggested, only 50% of the yield gains are related to hybrids. Adding hybrid technology alone could not have achieved these fantastic rates of gains; changes in management practices and the environment contributed to the other half of the story. Breeding efforts are confounded with climate and management changes in dynamic ways; breeding occurs over time in ever-changing environments and management.

2.01.2.2 Management

2.01.2.2.1 Planting Patterns: Plant Populations

One of the 'secrets' leading to the 2.0-2.5 bu acre^{-1} (125–157 kg ha^{-1} year^{-1}) increase in Iowa's trend-line yields for the last five to six decades – and similar increases in other states – is that breeders selected hybrid corn for increased yield per acre and not ear size. This resulted in greater stress tolerance as previously discussed in this chapter. Increased plant populations ranks among the more important stress factors.

Comparisons of 'checked' seeding rates with 42 inch (1.07 m) hills in Nebraska tests between 1914 and 1929 showed that stands between 2.5 and 3.5 plants per hill resulted in similar yields (Kiesselbach et al. 1935). Checked planting systems that dominated corn management systems in the Corn Belt through the mid-twentieth century consisted of equidistant spaced hills planted in a regular pattern that allowed mechanical cultivation either parallel or perpendicular to the rows as they were originally planted. By the end of the first half of the twentieth century, Ohio research showed that hybrids could tolerate 2000 plants acre^{-1} more than open-pollinated varieties; that allowed up to four seeds per hill (Kiesselbach 1950). They also recognized then that 15–20% of the seed would not emerge.

During the 1950s breeders made special efforts to produce hybrids suited for higher seeding rates without the risk of lodging and barren plants (Aldrich et al. 1975). Average Corn Belt plant populations in the mid-1970s reached 20 000 plants acre^{-1} with some at 24 000 (49 400 and 59 280 plants per ha, respectively). In the early 1980s, 24 000 plants acre^{-1} maximized yield for the best hybrids; today's hybrids require at least 35 000 plants acre^{-1} (86 450 plants ha^{-1}) for maximum yields (Elmore and Abendroth 2009). Iowa's corn plant populations increase about 400 plants acre^{-1} year^{-1} (USDA-NASS 2011). Modern hybrids withstand stress from higher seeding rates better than ever before.

These two factors – increased stress tolerance with modern hybrids and higher plant populations – are two of the many significant changes in corn management that fueled yield increases over the last half century. Regardless of climate, expect continued increases in seeding rates that maximize yields as breeders select hybrids in nurseries with successively higher and higher plant populations. Corn responses to factors like seeding rates are dynamically linked to climate during the breeding, testing, and selection processes.

2.01.2.2.2 Planting Patterns: Row Spacing

Row spacings varied little during the twentieth century until the 1960s. Prior to 1960, corn was mostly planted in check rows, which allowed for cross cultivation as explained above, with two or more seeds dropped into equally spaced hills. But some corn was 'drilled,' much as we plant today except with much lower seeding rates and wider rows. Comparisons of checked and drilled corn in Nebraska tests between 1922 and 1932 showed that yields were similar, 32.0 and 34.7 bu acre^{-1} (2.0 and 2.18 MG ha^{-1}) for checked and drilled, respectively (Kiesselbach et al. 1935). Drilled planting was a faster operation than check planting; in some situations such as contour farming – for conservation purposes – drill planting was a much simpler operation than check planting (Shedd et al. 1942).

By 1950, the need for 'precise planting' of corn, whether check planted or drilled, was still 'arbitrary' (Kiesselbach 1950); agronomists deemed optimum plant populations more important. For example, 42-inch rows (1.07 m) planted in the hill drop-check pattern were standard for the Iowa Corn Yield Tests from 1927 to 1949. In 1950, row widths in these trials dropped to 40 inches (1.06 m). Both 38- (0.96 m) and 40-inch rows were used in the trials in the 1960s. After that, row widths narrowed to 36 inches (0.91 m) and some to 30 inches (0.76 m) during the 1980s. Today, the yield trials are planted in 30-inch rows.

Thinking about narrow row systems as a way to increase corn yields is not new. Many innovators attempted planting corn in 15- or 20-inch (38–50 cm) rows as early as the 1960s across the Corn Belt. Planting and harvesting equipment were retrofitted for the systems, but, unfortunately, weed control was difficult with herbicides of that era. The system was not widely adopted until much later.

Early on, check-planted corn often out-yielded drilled corn, but it was later understood that weed control accounted for that advantage (Aldrich et al. 1975). Aldrich et al. (1975) also noted that although drilled corn provided more uniform plant distribution, it also increased tillering and lodging more than in checked corn. For these reasons, some farmers continued to check plant as late as 1975.

Row widths continue to decrease across the Midwest (USDA-NASS 2011). The row width reductions were in part due to the fact that yields in the mid-1970s were higher with 'narrow' rows – that is, 30-inch rows (0.76 m) – than wide rows – that is, 40-inch (1.01 m) rows (Aldrich et al. 1975). Current row widths employed by producers typically vary from 15 to 38 inches (0.38–0.97 m), with most Iowa producers planting in 30-inch (0.76 m) rows. Yet, some acres are planted to even narrower row widths. In general, this means 15 inches or 20 inches row widths or twin-row patterns. Twin-row configurations place two rows about 6–8 inches (0.15–0. 20 m) apart on 30-inch centers.

Numerous advantages other than yield exist for reducing row widths including using the same planting equipment for corn and soybean, reduced weed competition, increased shading of the soil, reduced evaporation, increased light interception per plant, and less in-row crowding. Since plant populations continue to increase, narrower rows provide plant placement more similar to equidistant spacing, which, in theory, should improve performance.

In general, greater yield response to narrow rows is expected to occur in northern US corn production areas, likely due to the shorter growing seasons and shorter stature hybrids in those areas. In general for Iowa, corn planted in rows narrower than 30-inches (76 cm) yield the same as those in 30-inch (76 cm) rows largely due to the near complete light interception with modern hybrids and plant populations in 30-inch rows at the key developmental stage of silking. It is important to note, though, that yields are not reduced when using narrow row widths relative to a 30-inch (76 cm) row; they yield the same.

Reductions in corn row spacing over the latter half of the twentieth century and into the early twenty-first century have served to increase yields through capturing more light at silking than is possible with wider rows. Further yield increases associated with narrower rows may not occur until seeding rates dramatically increase and/or plant architecture and, thus, the dynamics of canopy light interception are altered through changes in plant architecture. Changes in local and regional climate conditions would not likely affect these factors.

2.01.2.2.3 Planting Dates

Corn planting occurs earlier than ever before – to no surprise of most Corn Belt farmers and agronomists. Using data provided by USDA-NASS for Iowa, we clearly see that substantial changes occurred over the past three decades. One way to compare across the different periods of time is to look at the date associated with 50% of the acreage planted. For Iowa, the trend to earlier planting is consistent, 50% dates are earlier for each period compared to the previous except for two (1985–89 and 2005–09, the latter 5-year period affected by extremely late planting in 2008 due to wet conditions) (Figure 4). Iowa farmers planted their 2010 corn crop earlier than ever before recorded.

Numerous factors enable producers to plant their acreage earlier and faster. Wider planters with more row units, more cold-stress tolerant hybrids, improved seed treatments, global positioning systems, and reduced tillage systems, have each contributed to this change. As producers farm more acreage (see discussion below), they must naturally start earlier if they want the majority of their corn planted during the optimum planting window for their region (Abendroth and Elmore 2010). This recommendation is based on the fact that producers face a larger yield reduction by planting too late rather than too early.

Planting dates – the second week in May – and harvest dates – third to fourth week of October – of the Iowa Corn Yield Trials varied little from the late 1920s through the late 1960s (Table 2). These data take us back further in time than USDA-NASS data cited above and in Figure 4.

Stable planting dates during the first half of the twentieth century resulted in part due to interacting biological factors: weeds and the insect pest, ECB. Until wide-spread herbicide use, weeds were managed by several preplant tillage operations as well as two or more postemergence cultivations. Planting was delayed until tillage operations were completed and early flushes of weeds controlled. In addition, according to Kiesselbach (1950), ECB invasion affected thinking on the best planting time. Without the pest, anytime in May was suitable. In areas where ECB was a potential threat, Kiesselbach speaking to a national audience suggested a delay in planting until "mid-way in the normal planting season;" many waited until mid-May to start. Farmers and researchers heeded the advice; planting dates varied little over until 1960.

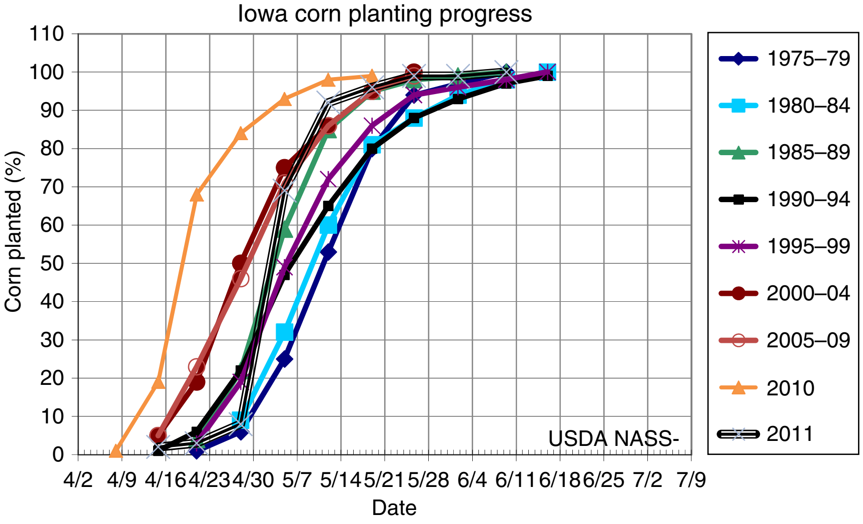

Figure 4 Iowa corn planting progress, 1975–2011. Data compiled from USDA-NASS.

Table 2 Multiyear average planting and harvest dates from Iowa's corn yield trials, 1928–2010

	Multiyear averages		
	Average date of planting	*Average date of harvest*	*Average difference, planting to harvest (days)*
1928–37	10 May	19 Oct	162
1938–47	14 May	27 Oct	166
1948–57	14 May	20 Oct	159
1958–67	13 May	26 Oct	166
1968–77	5 May	20 Oct	168
1978–87	5 May	17 Oct	165
1988–97	4 May	15 Oct	164
1998–07	1 May	10 Oct	163
2001–10	30 Apr	17 Oct	170

Since 1960, both planting dates and harvest dates of the Iowa Corn Yield Trials averaged about 2 days earlier for every 10 years while days between planting and harvest remained fairly consistent over time (Table 2). It is interesting that the period from days of planting to harvest has not dramatically changed in the last 50 years.

However, harvest dates do not represent the effective growing season – the period from planting to crop maturity; the Corn Yield Trials do not report dates of maturity, R6 (Abendroth et al. 2011). Fortunately, the percent of the crop at various developmental stages for Iowa corn 1981 to present are available from USDA-NASS (2011). An analysis of these data indicates that not only are planting dates and harvest dates getting earlier (as also shown in Table 2), but perhaps surprisingly, crop maturity dates are later. Since USDA-NASS records began in 1981, Iowa's effective growing season has increased about half a day every year (data not shown). No doubt these trends reflect the increased grain fill period and faster grain dry down with modern hybrids discussed relative to Table 1.

Early planting dates are expected, desired, and recommended in today's corn production systems. Although the period from planting to harvest is relatively stable, the effective growing season is increasing. Whether these trends in planting dates and growing season are associated with changes in weather patterns is difficult to sort out; again the two are confounded and affected by many other factors that changed during the latter half of the twentieth century and the early twenty-first century.

2.01.2.2.4 Nitrogen Use

Although synthetic N was developed during World War I, widespread use did not occur until after World War II (Paarlberg and Paarlberg 2000) (Figure 5). Indeed, research results from commercial fertilizer use before then were not encouraging. In Nebraska, Stewart et al. (1933) discussed rotations with a legume as essential to maintaining high soil fertility and high yields. They went on to say that "… commercial fertilizers on corn in Nebraska have usually failed to give increased yields sufficient to be profitable" (p. 27). But, in 1949, Nebraska farmers who side-dressed 40 pounds acre^{-1} (45 kg ha^{-1}) nitrogen averaged 60 bu acre^{-1} (3.8 Mg ha^{-1}), while controls yielded 35 bu (2.2 MG ha^{-1}) (Kiesselbach 1950). Iowa nitrogen fertilization experiments began in 1943 (Dumenil 1952). By 1952 in Iowa, N supply for corn came through legumes in rotation, manure, crop residues, and/or N fertilizers (Dumenil 1952). At that time, nitrogen application was in the form of either starter (4-16-8) or side-dress – (ammonium nitrate, urea, etc.). Crop rotation was still the backbone of recommended practices.

Nitrogen use in Iowa did not dramatically increase until the late 1940s. From the mid-1950s through 1975, anhydrous ammonia was the most often used N source (Aldrich et al. 1975). From 1961 to 1980, N sales in Iowa annually increased by over 47 000 tons year^{-1} (42.6×10^3 MG). The trend of increasing N application stalled in 1981 when more than 1.16 million tons (1.05×10^6 MG) were sold. Educational efforts on the part of extension specialists and others in regard to environmental concerns as well as economics, and other forces likely served to level the trend of nitrogen sales for the 1980s until now. Extremes on the recent plateau of N sales include 1983 PIK (Payment in Kind), 1988 drought, and 1993 flooding. 'Payment in Kind' was a 1983 US government program to

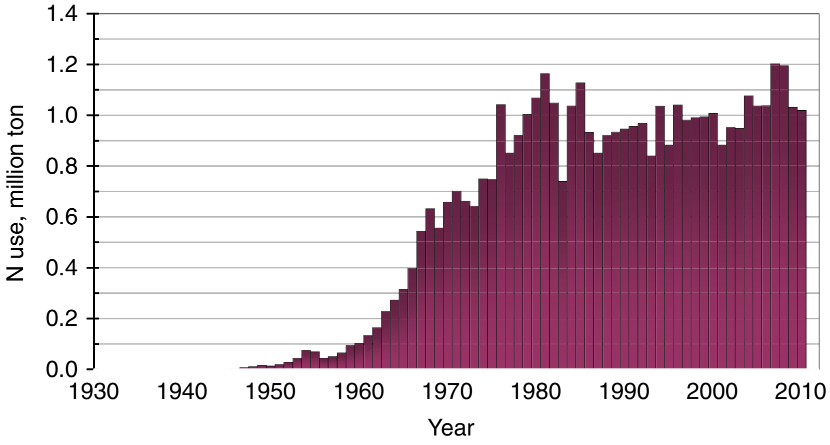

Figure 5 Annual nitrogen sales in Iowa. From John Sawyer, Iowa State University Extension.

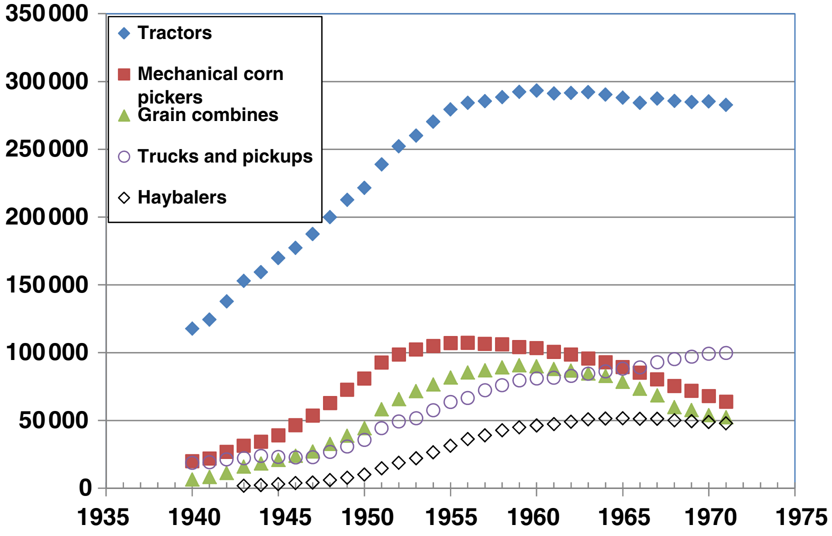

Figure 6 Mechanization of agriculture in Iowa, 1940–71. Numbers of units. Iowa farm census.

help reduce grain surpluses and improve farm income. In the 1983 PIK year, planted corn acres in Iowa fell to below 10 million acres for the first time since 1950.

Nitrogen application affected corn yield trends. From 1950 to 1977, US corn yields increased at a rate of 2.2 bu acre^{-1} year^{-1} (138 kg ha^{-1} year^{-1}). Sinclair and Sinclair (2010) suggest that a cornerstone in the yield increases up to the mid-1970s was the increased supply and application rates of nitrogen (p. 171). They were quick to state that plants genetically suited to take advantage on increased N were developed in tandem with increased N rates. When increases in N application leveled off in the 1980s, so did the rate of corn yield increases. From 1978 to 2010, yields increased 1.9 bu acre^{-1} year^{-1} (119 kg ha^{-1} year^{-1}).

With these trends and the recent plateau in N application in mind, we can rule this as a variable confounded with climate since the early 1980s. However, potential increases in hybrid N-use efficiency (Sinclair and Sinclair 2010) may still result in a confounding of N fertilizer and climate trends.

2.01.2.3 Mechanization and Farm Numbers/Sizes

> Commercial corn production cannot be carried on by hand methods. It can only be done with machinery.
>
> (Shedd et al. 1937)

My great grandfather Mayne was an Illinois farmer, horse, and teacher. In 1904, influenced by his interest in horse-centered agriculture, he said, "I hope the day is far distant when the use of automatic or electrical devices will supersede [the] use [of work horses]." He lived to see the day – which was far distant – when horses were no longer necessary for agriculture to progress. Unfortunately, I was too young to ask what he thought about it.

Mechanization quickly took over the horse power needs of agriculture as great grandfather Mayne feared (Figure 6). Although mechanization was a time saver, it sometimes had drawbacks. According to Shedd et al. (1937), harvesting 70 bu acre^{-1} corn (4.4 MG ha^{-1}) by hand took 9 man hours acre^{-1} (22 h ha^{-1}), whereas it took only 2.5 man hours acre^{-1} (6 h ha^{-1}) with a machine. The down side was that harvest losses were greater with machine than with hand harvest. Those losses were sometimes considerable. Kiesselbach (1950) noted that mounted picker losses with 15% grain moisture were 15%. In addition, 13% of the harvested grain was loose, that is not attached to ears and thus at risk of possible lost in handling and storage (Kiesselbach 1950).

Nevertheless, mechanization saved farmers considerable time and resources. Leonard and Martin (1963) reported that in 1800, a 25 bu acre^{-1} (1.6 MG ha^{-1}) corn crop required 80–90 h of labor per acre^{-1} (200–222 h ha^{-1}), all by hand. By 1870, improved plows and cultivators lowered the labor requirement to 40–70 h acre^{-1} (100–172 h ha^{-1}). By 1890–1910, manual labor requirement was down to about 15 h acre^{-1} (37 h ha^{-1}) with the help of horse-drawn two-row planters and cultivators. By 1945, labor required was 5 h acre^{-1} (12 h ha^{-1}) with machines. Recent innovations in global positioning has allowed a new wave of technology with guidance systems potentially reducing operator fatigue and improving production efficiency perhaps even more than mechanization itself. Since 1945, labor requirements per acre have dropped even more: 1979, 3; 1986, 3; 1996, 1 (Duffy 2009).

Coupled with increased mechanization (at least in Iowa) was a massive decline in farm numbers; farm numbers declined from 215 000 in 1940 to 92 500 in 2010, a loss of about 2100 farms per year (Mike Duffy, ISU, personal communication, 2011). Not only did farm sizes increase but also farmers became more specialized. Early-on, farmers managed multiple crops in diverse cropping systems (corn, soybeans, wheat, oats, alfalfa, clover, etc.) as well as maintaining multiple animal production enterprises (cattle, horses, hogs, sheep, goats, chickens, turkeys, etc.). Today, many Iowa farm operations concentrate on either livestock or crops, with crop-focused farms usually containing only corn and soybeans. Increased farm sizes can result in a subsequent improvement in production efficiency, due to economies of scale, to a certain point beyond which it decreases (Duffy 2009).

Trends to larger farm sizes may ebb a bit based on findings of a recent study using longitudinal agricultural US census data (Melhim et al. 2009). They found that growth rates of large corn farms – as measured by farm income – were less rapid than smaller farms. Corn farms may be reaching or have already reached an equilibrium size. They also found that economies of scale diminished between 1987 and 2002, suggesting that larger farms became less efficient than smaller ones. This supports the comments from Duffy (2009), as previously mentioned. Because of this, Melhim et al. (2009) suggested large farmers approach expansion with caution. Economies of scope for corn producers, however, were similar regardless of farm income; corn farms became less diversified over time because there was little incentive to diversify, that is, to include more crops or products in their operations.

Increased mechanization in farming operations no doubt increased fossil fuel use and CO_2 emissions. But, at the same time, as farmers became more specialized, they improved yields per unit area and increased farm sizes. Recent research suggests increases in farm size may have slowed as just discussed above (Melhim et al. 2009). In any case, increased mechanization has been correlated with increased yields and climate. Correlations do not suggest cause and effect.

2.01.2.4 Weeds, Tillage, Insects, and Diseases

> When tillage begins, other arts follow. The farmers therefore are the founders of human civilization.
>
> (Daniel Webster)

> Weed growth was somewhat more effectively controlled in check-planted corn. … weed control is becoming a more serious problem in Iowa from year to year. … the area of distribution of perennial weeds has been increasing rapidly.
>
> (Shedd et al. 1937)

> Weeds rob the crop of moisture and nutrients.
>
> (Kiesselbach 1950)

2.01.2.4.1 Weed Control and Tillage

Prior to herbicides, the best weed management was tillage, smother crops, poisoning (with certain chemicals), and eternal vigilance among other methods (Shedd et al. 1942). In 1942, E. J. Kraus, University of Chicago, developed 2,4-D, an effective postemergence herbicide for controlling broadleaf weeds (Paarlberg and Paarlberg 2000). Although 2,4-D had proven itself able to control broadleaf weeds without injuring corn by the late 1940s, scientists still considered herbicides as tools to supplement other proven methods of weed control: tillage and crop rotation. There was yet no great interest in preemergence herbicides. Nevertheless, it was understood, at least by some, that, "In most soils, deep plowing is not advantageous and needlessly adds to the expense by way of increased power requirements" (Kiesselbach 1950). By 1963, herbicides were still considered as 'useful supplements' to mechanical weed control and not as complete replacements for it (Leonard and Martin 1963).

The role of herbicides in cropping systems has dramatically changed since 1963. "The nearly complete reliance on herbicides on corn contributed to the developments of current 'conventional cropping systems' that include large-scale production enterprises utilizing high-yielding varieties … and high inputs of chemical fertilizers and pesticides on the most fertile, productive soils available" (Kremer 2004). Certainly though, nearly complete reliance on herbicides resulted in herbicide resistant weeds (Owen 2005).

Reduced tillage systems are now common. As of 2008, tillage systems leaving more than 30% residue on the surface covered 40% of US acres. Another 24% of our tillage systems left 15–30% residue on the surface. Only 36% of the acres were 'conventional till' leaving less than 15% residue (CTIC 2011). No-till and reduced tillage systems depend on herbicides and machines capable of handling large amounts of residue. Reduced tillage systems control both wind and soil erosion and conserve soil moisture. The latter is especially critical in dry years and dry environments.

In the last 50 years, most US corn production systems progressed from using herbicides as 'useful supplements' to herbicides as necessities for most producers. Improved weed control associated with good herbicide management undoubtedly contributed to corn yield increases. Now, weed resistance to herbicides concerns most producers and agronomists. Herbicides allow us to plant corn earlier than ever before permitting us to take advantage of earlier springs.

2.01.2.4.2 Insects and Diseases

Seed disinfectants and protectants in the 1940s improved grain yields in most situations but more so with early planting dates and wet soils, which were not too common (Kiesselbach 1950). Today, virtually all corn planted has seed treatments that control soil-borne insects and pathogens.

In 1935, Paul Müller working with the Swiss company, J. R. Geigy, developed DDT that was widely used by Allied soldiers in World War II. US The farmers recognized the promising role DDT could play in crop production systems and 'quickly expanded its use' (Paarlberg and Paarlberg 2000). Various Bt transgenic insect resistance traits have largely replaced specific insecticide applications.

Postemergence fungicide applications for control of foliar diseases became more common in the last 4–5 years in part due to high corn prices, fungicide availability, and foliar disease pressure. By 2010, 14.6% of the US Corn Belt's 38.6 million acres (15.6×10^6 ha) of corn were treated with fungicides (USDA ERS 2011). Fungicide-use figures were not available in prior USDA ERS reports mostly likely because their use on corn – other than for seed treatments – was negligible prior to 2007.

Fungicides at least in Iowa are often applied to corn after tasseling (VT) in large part to manage the foliar disease Gray Leaf Spot (GLS caused by *Cercospora zeae-maydis*). Although GLS was first identified in Illinois in 1924, prior to 1988 it was not considered economically important although localized outbreaks had occurred (Ward et al. 1999). A dramatic increase in prevalence across the Corn Belt occurred from 1988 to 1995; yield losses up to 50% were reported. Specific corn hybrid vulnerability to GLS was known: a study in the early 1980s found that most Corn Belt hybrids were either highly or moderately susceptible to GLS (Ward et al. 1999).

Moderate temperatures (70–90 °F; 25–32 °C) and prolonged periods of cloudy days, and 12 h of free moisture on leaves with high relative humidity in crop canopies (>12 h at >90% RH) are conducive for GLS epidemics (Rees and Jackson 2008). Since the pathogen survives in crop residue (it is wind borne as well), reduced tillage systems and increased corn following corn in rotation systems have likely contributed to increased GLS problems in the central and western Corn Belt. Increased plant populations reduce airflow in crop canopies and may contribute to this disease.

Disease infections require a susceptible host, the pathogen, and a favorable environment. All of these elements came together 1988–95 spurring the GLS epidemic. Climate may have impacted disease infections.

Advances in Corn Production in the US Corn Belt: Summary

It is incorrect to suggest that increases in corn yield since the 1940s are the result of breeding efforts. Likewise, it is incorrect to suggest that increases in corn yield are the result of climate change – or for that matter improved management practices. The increases are a direct result of multiple factors and events coinciding midway through the twentieth century and continuing to this day. Our challenge – vulnerability – is to continue the trend of increasing yields well into the twenty-first century.

2.01.3 Vulnerabilities

> Changes in temperature, CO_2, and precipitation under the scenarios of climate change for the next 30 years present a challenge to crop production.
>
> (Hatfield et al. 2011)

2.01.3.1 Climate and Impacts on Corn Production

Continuing changes in atmospheric CO_2 concentration, and possible changes in temperature and precipitation, impacts corn production to varying degrees. Doubling CO_2 concentrations from ambient levels in research studies increased corn's leaf photosynthesis by 3% and total biomass and grain yield by 4% (Hatfield et al. 2011). In contrast, the same physiological variables of soybean increased by 35 and 37%, respectively. Corn, like other C_4 photosynthetic pathway crops, responds less to CO_2 increases than C_3 crops like soybeans. Fortunately, C_4 crops are less sensitive to increases in ozone than C_3 crops. Specifically, Hatfield et al. (2011), in their review paper, estimated that an increase in CO_2 from 380 to 440 μmol mol^{-1} would increase Midwest corn yields by 1%. But, increases in CO_2 may also reduce grain protein and increase grain carbohydrates (CSSA 2011). These changes would possibly have negative effects on the livestock industry but positive effects on the ethanol industry. In the latter case, ethanol production stems from kernel carbohydrates. On the other hand, reduced grain protein means that livestock producers will need to supplement grain protein in rations from other sources.

Temperature increases would likely have a greater negative effect on corn than elevated CO_2 itself. Current Midwest temperatures are optimum for corn production while those of the South already exceed optimum (CSSA 2011). Where temperature is the only limiting factor, a temperature of 93 °F (34 °C) is optimum for both vegetative and reproductive growth (Hatfield et al. 2011). For comparison, soybeans perform better in slightly cooler conditions with optimum vegetative development at 86 °F (30 °C) and optimum reproductive development at 79 °F (26 °C). Higher temperatures hasten corn developmental stages. Faster development especially during seed fill means reduced yield potential (Elmore 2010). This effect is compounded when coupled with drought. Pollen viability drops with temperatures greater than 95 °F (35 °C); a temperature of 95 °F (35 °C) reduces kernel growth rate and eventually kernel size compared to a temperature of 86 °F (30 °C) (Hatfield et al. 2011). Hatfield et al. also reported that photosynthetic rates drop above 100 °F (38 °C) and estimate that a temperature increase of 1.4 °F (0.8 °C) will lower irrigated corn yields by 2.5% in both the US Midwest and in the South. When increased temperatures (1.4 °F (0.8 °C)) are coupled with increased CO_2, corn yields in both US regions are reduced by 1.5% (Hatfield et al. 2011). However, Hatfield et al. remind us, "We are in an era of uncharted responses …."

Drought is obviously a major factor in yield variability. One has only to look at corn yields for the drought years of 1983 and 1988 in Figure 1 to recognize this. Increased greenhouse gases could result in more agricultural droughts (Hatfield et al. 2011). In addition, Hatfield et al. note that more frequent high-precipitation events (>2 inches (5 cm) in 48 h) may result in the inability of some soils to rapidly infiltrate water. This inability of some soils will reduce soil moisture available for crops and, thus, encourage the need for cultivars that conserve water and maintain yield (CSSA 2011).

In addition to the impacts on corn, climate affects weeds, insects, and diseases. Increased CO_2 may result in increased weed competition and thus reduced grain yields. In addition to that, Hatfield et al. report that many studies demonstrate declines in pesticide efficacy with higher CO_2. Insect ecology is also affected by temperature while plant pathogens are affected by a combination of temperature, humidity, and precipitation (Hatfield et al. 2011). Warmer less severe winters may increase insect and disease survival over winter (CSSA 2011) although, again, we are in uncharted territory (Hodgson 2012).

To feed our continued population growth, yields must continue to increase, in the face of plausible future climate conditions. Is that possible in corn?

2.01.3.2 Continued Yield Increases? Doubling Yield by 2030?

Subtle changes in tides occur along coastlines in most parts of the world. A necessary line in the sand marks its inevitable rise and fall. Certainly drastic 'sea changes' occur – remember the word Tsunami? I am often asked if the US average corn yield will reach 300 bu acre^{-1} (18.8 MG ha^{-1}) by 2030. For that to happen, a profound transformation, a paradigm shift – a sea change – must occur to reach a national or, for that matter, Iowa state average yield of 300 bu acre^{-1} in less than two decades.

Promises abound for reaching 300 bu acre^{-1} and/or doubling today's yields by 2030. Both producer and general public expectations rise like the tide with these promises. Iowa corn yields are increasing at more than 2 bu acre^{-1} year^{-1} (125 kg ha^{-1} year^{-1}), as previously mentioned, with the 2009 state average at 182 bu acre^{-1} (11.4 MG ha^{-1}) the highest ever recorded. It is possible for the average US corn yield to reach 300 bu acre^{-1} by 2030 but only if the rate of gain is more than tripled from its current increase of 2 bu acre^{-1} year^{-1} (125 kg ha^{-1} year^{-1}) to over 7 bu acre^{-1} (440 kg ha^{-1} year^{-1}) starting now. That magnitude of change seems very unlikely.

Some producers indeed successfully produce very high yields now. The National Corn Growers Association (NCGA) celebrates yield contest winners each year whose corn crops yield from 250 to well over 400 bu acre^{-1} (15.7 to 25 MG ha^{-1}). These top producers with premier environments prove that 300 bu yields per acre (18.8 MG ha^{-1}) are possible with today's genetics coupled with excellent management and environments, but, on a relatively small scale. Few producers have this unique combination of factors.

Unfortunately, a limit to yield may exist. This is a significant concern among agronomists who suggest that top yields of NCGA contest winners stabilized more than 30 years ago (Duvick and Cassman 1999). These elite corn growers with premium environments reported similar yields in the late 1990s as those reported as early as 1985 (370 bu acre^{-1}, 23.2 MG ha^{-1}). However, a recent examination of current yield data from NCGA contest winners suggests that the yields of all first to third place winners since 1988 continues to increase about 2.5 bu acre^{-1} year^{-1} (157 kg ha^{-1} year^{-1}), whereas that of the highest yield in the contest each year increases about 3.7 bu acre^{-1} year^{-1} (232 kg ha^{-1} year^{-1}). These data do not appear to support the hypothesis of a yield ceiling.

Meanwhile, however, recent yields of irrigated NCGA contest winners in Nebraska have leveled off much as Duvick and Cassman (1999) noted more than 10 years ago while yields of dryland contest winners increase at 1.8 bu acre^{-1} year (113 kg ha^{-1} year^{-1}) (data not shown). Nebraska state averages for irrigated and dryland corn producers continue to increase at 2.2 and 1.6 bu acre^{-1} year^{-1}, respectively (138 and 100 kg ha^{-1} year^{-1}, respectively) (USDA-NASS data, trend lines from 1947). The exploitable yield gap between attainable rainfed and irrigated systems is disappearing in Nebraska. Duvick and Cassman's (1999) statement still applies: "The trends … suggest that attainable yield levels in rainfed [dryland] systems … are converging on the attainable yield level of irrigated systems and the later appears to represent a yield ceiling in production-scale fields."

Other corn producers have access to the same genetics as contest winners. Even the best hybrids will produce average yields when coupled with average management and average environments. Solving the yield puzzle will come only with more completely understanding the interaction of these three factors. But wait a minute – aren't dramatic changes being forecast in hybrid development with transgenics? As mentioned above, while transgenic hybrids protect yield, whether herbicide or insect resistant, they do not increase yield potential. A drought gene may add another tool to help protect yield potential, not increase it.

Unfortunately, several forces work to reduce annual yield gains. For example, the current trend for more corn-on-corn – due to market incentives – will pull down averages because of inherently lower yields when corn follows corn in a cropping sequence. With higher prices for corn, less productive soils are brought into production, again lowering average yields. In addition, yield trend increases will likely lessen rather than increase since farmers already use many yield-increasing practices. For example, farmers, in most cases, control weeds and insects better than ever before, and the predominant central Corn Belt row spacing of 30 inches (0.76 m) maximizes yield. Certainly though, continued improvements in weed and insect management as well as other cultural practices are necessary. However, we should expect smaller yield gains from these changes than previously experienced.

We must address increased yield and yield potential from two approaches – both breeding and management. Seed companies focus on breeding and hybrid improvement. Solely trusting on breeding efforts to move yields to the next level is disconcerting. A singular focus on the seed will stymie progress. Dramatic changes in corn yields over the past six decades came from intensive research efforts in both breeding and management, plus a largely favorable environment.

Without a dramatic change (a sea change), US average yields may reach 300 bu acre^{-1} (18.8 MG ha^{-1}) in six decades but may level off at some point before that. That is far behind the pace that numerous groups have promised and many people would like to see.

The slow but consistent increases in the tide of corn yields experienced over the years will hopefully continue; but I cannot say that with confidence. Breeding and management research, and the funds to do it, are necessary. Without this two-pronged approach, the 300 bu acre^{-1} line in the sand will take many decades to reach.

2.01.4 Opportunities and Concerns

Climate effects are not new, neither is the farmer's ability to adapt. Kiesselbach (1950) spent a good deal of a paper presented at the 1950 American Seed Trade Association meetings discussing soil erosion. He mentioned that during World War II the need for maximum total production encouraged bringing marginal lands into cultivation. He stated, "This land should be grass in peace times … One's very soul cries out against the erosion and lack of preventive measures in many fields as one traverses the countryside. On such farms is there not thought of the morrow?" We adapted; in 2008, as previously mentioned, nearly 2/3 of the US had at least 15% residue cover after planting.

By 1950, the highest state average yield recorded was 160 bu acre^{-1} (10 MG ha^{-1}) from both Iowa and Illinois with a normal range of 20–75 bu acre^{-1} (1.25–4.7 MG ha^{-1}) (Kiesselbach 1950). Kiesselbach by 1950 had witnessed an increase in US average corn yields from 26 bu acre^{-1} (1.63 MG ha^{-1}) to a 9-year average of 35 (2.19 MG ha^{-1}) in

1941–49. He predicted an increase of 60% in 25 years; going from 35 bu in the 1940s to 60 bu acre^{-1} (3.76 MG ha^{-1}) by 1975. He would be surprised to see that the combination of all factors increased yields far more than he expected; the 1975 average US corn yield was 86 bu acre^{-1} (5.39 MG ha^{-1}), double the increase from what Kiesselbach expected! How much higher can yields go especially in the light of climate change? I am often reminded, "Don't bet against technology!" (Kendall Lamkey, personal communication, 2011).

Genetic, management, and environmental changes working together – and at times in opposition to each – over the last six decades resulted in incredible unprecedented gains in corn productivity. For these trends to continue, we must focus on breeding for yield – as well as protecting yield, paying close attention to and adapting management practices, and be ever vigilant to subtle barely perceivable changes in local and regional weather patterns.

These three causes interact, together, inseparable, as a seed and its fruit. Let us do our best with what we have, manage what we can, control what we have to – and can – control, with a focus on conducting adaptive research, teaching the best science, extending information, and mitigating and adapting to climate so subsequent generations are prepared to feed themselves.

2.02.1 Introduction

The main climate vulnerability that soybean faces in the future is the same one it has been facing since agriculture began – unpredictable and insufficient precipitation. Heavy precipitation events are problematic, and their frequency has been forecast to increase in the future (Meehl et al. 2007; Gutowski et al. 2008), but drought constitutes the greatest threat to soybean and most other crops (Purcell and Specht 2004; Sinclair 2011). Crop production without irrigation is water-limited to a significant extent at present compared with theoretical full potential (Rost et al. 2009). In the future, regions of major soybean production in the United States may experience mild drying during the growing season according to IPCC top-down multi-decadal model projections, due to increased evaporation with higher temperatures (Meehl et al. 2006; Christensen et al. 2007; Dai 2011). Soybean breeding and management strategies appear capable of coping with higher temperatures and longer growing seasons (Sinclair 2011). Rising atmospheric CO_2 concentrations will likely stimulate growth and yield, as well as ameliorate negative impacts of air pollutants such as ozone. Increased frequency of heavy precipitation events is likely to exacerbate runoff, but water deficit at crucial times in the growing season can be devastating. Improving soybean tolerance to water stress and its interaction with heat stress should be emphasized (Purcell and Specht 2004).

2.02.2 Background

Soybean is the major oilseed produced and consumed in the world (Wilcox 2004). Worldwide, soybean is ninth in production tons among crops, with a gross production value of US$79 billion in 2009 (FAO 2009). The largest producers of soybean are the United States, Brazil, and Argentina, accounting for 80% of the world's production (223 million metric ton (MT) in 2009) (**Table 1**) (FAO 2009). China and India produce 11% of the world's soybeans. Expansion of oil crop production has been very rapid in recent decades, which accounts for a large share of the expansion of the world's agricultural land, with a net increase of 75 million ha between 1974–76 and 1997–99. Current production is up from 42 million MT in 1970. Seed yields of soybean have increased about 1% per year in the major soybean-producing countries. Brazil has the greatest potential for expanding soybean production areas (Wilcox 2004).

In the United States, soybean is grown in the eastern half of the country where adequate moisture is available for successful crop production. Soybean production has been made profitable in the Central Plains and mid-south through the use of irrigation (Heatherly and Elmore 2004). The north-central states produce 82% of the total production in the United States (Wilcox 2004). Iowa, Illinois, Minnesota, Indiana, Nebraska, Missouri, and Ohio are leading producers in the northern United States, while Arkansas, Mississippi, and North Carolina are leading producers in the southern states. Soybean is mainly grown as a full-season, spring-seeded crop, although about 9% is planted as a second crop, following winter wheat, rice, or winter canola, south of 35° N latitude (Wilcox 2004).

Brazil's soybean production is concentrated in two main regions, the South and the Center-West (Wilcox 2004). The South has been the historical center of Brazil's soybean production. It includes the states of Parana and Rio Grande do Sul. Center-West includes the states of Mato Grosso, Mato Grosso do Sul, and Goias. The South has semitropical and the Center-West has a tropical climate. Brazil is generally milder and wetter than the United States and temperatures vary little throughout the year. Monthly average temperatures range 17–24 °C in Parana and 23–28 °C in Mato Grosso. Crop production in Brazil and Argentina is about 6 months later than in the United States.

In Argentina, soybean production is mainly in the provinces of Cordoba, Santa Fe, Buenos Aires, and Entire Rios in the

http://dx.doi.org/10.1016/B978-0-12-384703-4.00204-5

central-eastern region of the country, the Pampas (Wilcox 2004). The region is temperate-humid with an annual mean temperature of 17 °C in the north and 14 °C in the south (Magrin et al. 1997). Mean rainfall varies from 110–130 mm in November to 70–140 mm in April, with considerable year-to-year variation (Penalba et al. 2007).

2.02.3 Warming Temperature

Global-scale and sub-global studies have detected the influence of anthropogenic forcing on the twentieth century near-surface temperature changes that is inconsistent with natural forcings alone (30; NRC 2005), although there is also research that attributes a significant fraction of the observed temperature variations to natural climate forcings (Wyatt et al. 2011). Future climates could therefore be warmer regardless of the cause (Figure 1) (Meehl et al. 2007). By mid-century (2046–65), the magnitude of multi-model globally averaged surface air temperature (SAT) warming is estimated by the IPCC as +1.3, +1.8, and +1.7 °C from the AOGCMs for B1, A1B and A2 IPCC SRES emission scenarios, respectively (Meehl et al. 2007). Geographical patterns of projected SAT warming from these models predict the greatest temperature increases over land (roughly twice the global average temperature increase) (Meehl et al. 2007). Large regional changes that include possibilities of both warming and some cooling are also possible – along with increases in diurnal and longer term variability (Lovejoy and Schertzer 2012).

North American observations show a general increase in the number of warm nights (Gutowski et al. 2008). Growing season length is also increasing. The 1-week increase in growing season length observed over the twentieth century could be 2-weeks longer by the end of the twenty-first century (Gutowski et al. 2008). In a warmer climate, there would also be an increased risk of more intense, more frequent and longer-lasting heat waves (Meehl et al. 2007).

Multiple regression analysis of climate and global soybean yield data for 1961–2002 showed a positive relationship with precipitation and a negative one with warming (Lobell and Field 2007). It was suggested that increased crop development rates, water stress, and canopy respiration could be responsible for the trends observed. Multiple regression analyses showed that soybean in the humid Argentine Pampas was sensitive to a higher maximum temperature during summer months and rainfall excesses in the maturity-harvest period, which resulted in a lower yield (Penalba et al. 2007). A higher minimum temperature during the growing season increased yield. The most significant spatial coherence with yield was seasonal precipitation, which can be considered a proper yield indicator (Penalba et al. 2007).

The growing temperature range (mean daily air temperature) for soybean is 20–30 °C (Allen and Boote 2000). However, low nighttime temperatures (<12 °C) and high daytime temperatures (>36 °C) can limit production (Allen and Boote 2000). Net photosynthesis increases with temperature to about 40 °C (Allen and Boote 2000). In outdoor controlled-environment chambers, whole-canopy photosynthesis rates (and vegetative growth) were maintained at 44/34 °C sinusoidal maximum–minimum (day/night) temperatures (Allen and Boote 2000). Reproductive development is strongly dependent on temperature, with delays to reach pod

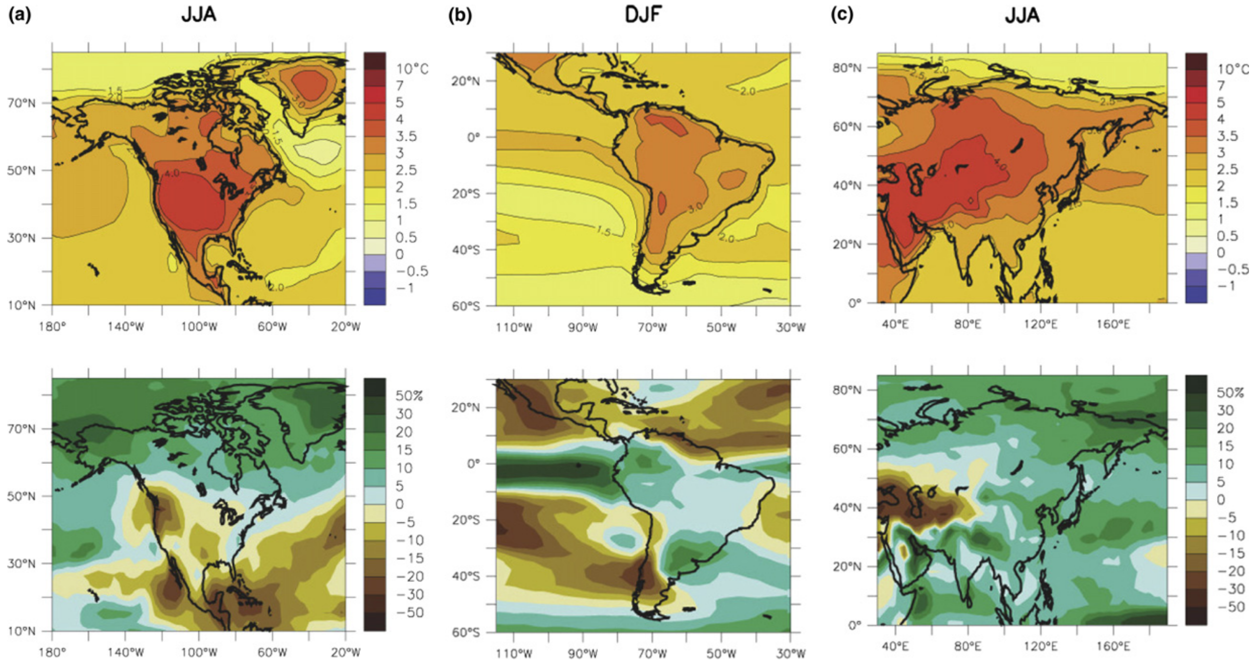

Figure 1 Projected changes in temperature (upper panels) and amount of precipitation (lower panels) during 3 months of the soybean growing season in North America (a), South America (b), and Asia (c) between 1980–99 and 2080–99, averaged over 21 general circulation models (A1B scenario) (Christensen et al. 2007). This is an example of the top-down approach where the vulnerability starts from the multi-decadal global climate model prediction. As such they should be interpreted as, at best, a subset of what is possible in the coming decades. IPCC Fourth Assessment Report, Climate Change 2007 (AR4).

maturity (R7) when mean daily temperatures >31 °C (Allen and Boote 2000). In general, soybean, along with most warm-season seed crops, produces fewer viable seeds as air temperatures increase above an optimum mean daily temperature of about 26 °C (Allen and Boote 2000).

With regard to the effect of warming on soybean reproduction, flowering is flexible. There are three racemes per node, and if flowers abscise due to heat stress, the other racemes can produce blossoms when high temperatures subside. Heat waves per se will not be a threat to seed production, but they can make water stress worse (T.E. Carter, personal communication) – and vice versa; i.e., the heat stress can be worse under water stress. Farmers can adapt to warmer temperatures – seasonally or in the long run – by planting earlier with the appropriate soybean maturity group, as shown by the successful early soybean planting system (ESPS) (see below) (Heatherly and Elmore 2004).

2.02.4 Drought

Studies have concluded that there is an increasing occurrence of hydrological extremes and variability (refs). There are studies that conclude, based on top-down global multi-decadal model predictions, that the future climate is expected to have higher moisture content (Meehl et al. 2007). The increase in water-holding capacity of the atmosphere would likely increase the frequency of heavy precipitation events, as extreme precipitation is constrained by the atmospheric moisture content (Meehl et al. 2007). There is also a trend for increasing dry periods between rainfall events, although models are less consistent about this (Meehl et al. 2011). There has been a long-standing projection by climate models for increased summer drying in the mid-latitudes, with an associated increased probability of drought (Meehl et al. 2007; Dai 2011). Soybean-producing regions in the United States could experience decreased precipitation ranging from 5 to 10% during summer months by the end of this century (Figure 1) (Christensen et al. 2007). Aridity is projected to increase in soybean-growing regions in the Americas (except northeast Argentina and Uruguay) and Southeast Asia due to the effects of regional warming attributable at least in part to anthropogenic greenhouse gas emissions (Dai 2011). Global crop net primary production decreases by 10% with the climate expected with the SRES A2 emission scenario by 2050 due to regional precipitation declines, higher temperatures that lead to higher crop water limitation, and direct crop damage (Rost et al. 2009). Elevated CO_2 offsets these negative effects, but the magnitude of the effect is uncertain. Increased moisture content of atmosphere would dampen the effect of warming on vapor pressure deficit, which increases exponentially with temperature and drives transpirational water loss from plants, but some increase in evapotranspiration may occur nonetheless. However, simulation studies may have overestimated the impact of high temperature on crop water use by not accounting for increases in vapor pressure (Sinclair 2011).

Soybean yield, like many crops, is highly sensitive to water availability, which is mainly determined by precipitation and temperature (Purcell and Specht 2004; Penalba et al. 2007). Interannual variability of soybean yields in Argentina was generally accompanied by interannual variability in seasonal precipitation (Penalba et al. 2007). Higher rainfall anomalies during the maturity-harvest period had a negative impact on yield, possibly related to disease, flooding and failed harvests (Penalba et al. 2007).

Seed yield (Y) has been shown to be related to plant traits and physiology in water-limited environments through the following relationship:

$$Y = T \times \mathrm{WUE} \times \mathrm{HI},$$

where T is the amount of water transpired, WUE is the water use efficiency, and HI is the harvest index (Purcell and Specht 2004). In this relationship, T refers to the total quantity of water transpired by the plant from emergence to physiological maturity. Production WUE refers the relative amount of shoot biomass or seed produced per unit of water transpired. At the physiological level, WUE is defined as the ratio of net photosynthesis to transpiration, also referred to as transpiration efficiency. HI refers to the ratio of grain mass to total shoot mass. Plant traits that increase any of the factors in the above equation have the potential to increase plant yield under water stress conditions (Purcell and Specht 2004).

Studies have focused on a number of genetic, physiological, morphological, and developmental and management approaches to increasing soybean drought tolerance (Purcell and Specht 2004). Yield can be increased in water-limited environments by increasing transpiration. This has been successfully accomplished with the ESPS that is utilized in the mid-south region of the United States (Heatherly and Elmore 2004). Yield losses due to dry, hot late-season conditions in Arkansas, Mississippi, Louisiana, and Texas have been reduced by planting in the spring when precipitation sufficient for crop growth is more likely and cooler temperatures decrease evaporative demand. Early maturing soybean cultivars are used to better match phenology with available water (Purcell and Specht 2004). Minimum tillage and cover crops are also used to increase soil organic matter, which can increase soil volumetric water content and help conserve soil moisture (Purcell and Specht 2004). Deeper rooting assisted by osmotic adjustment of roots to maintain cell turgor, when tissue water potential declines, has promising potential for improving transpiration and yield as well (Purcell and Specht 2004). Improved tolerance to aluminum, which is found in toxic concentrations in lower soil horizons, has been associated with drought tolerance in a slow-wilting genotype. Tolerance to aluminum was correlated with the concentration of citrate in root tips, suggesting that citrate release was involved in aluminum exclusion in tolerant genotypes (Silva et al. 2001). Breeding and genetic modification for this trait may be beneficial.

Improved WUE is expected to occur with increasing atmospheric concentrations of CO_2 because net photosynthesis is higher and transpiration is lower due to reduced stomatal conductance (Allen and Boote 2000). Both factors would contribute to yield increases in soybean. However, reduced transpirational cooling leads to higher leaf temperatures and leaf-to-air vapor pressure deficits, which increases transpiration and respiration, thus decreasing net crop biomass gain. Water stress increased leaf temperature and leaf-to-air vapor pressure deficit in soybean plants (Allen et al. 1994). Management practices employed in ESPS also increase WUE by growing plants when evaporative demand and VPD are decreased by cooler temperatures (Purcell and Specht 2004).

The most sensitive component of soybean biology to drought stress may be nitrogen fixation by symbiotic *Bradyrhizobium japonicum* bacteria in root nodules (Purcell and Specht 2004; Sinclair et al. 2010). Nitrogen fixation is more sensitive to water deficit than many other processes, including photosynthesis, biomass production, transpiration, and nitrogen uptake from the soil (Purcell and Specht 2004). Increased concentrations of nitrogen compounds (ureides) in water-stressed plants suggested that nitrogen fixation is inhibited by feedback regulation of nitrogenase activity in the nodule (Serraj and Sinclair 2003). Factors that decrease nitrogen supply to soybean invariably impact seed yield because the high protein concentration of soybean grain requires a large amount of nitrogen. Prolonging nitrogen fixation during water stress could prevent premature senescence and improve HI, thereby increasing yield (Sinclair et al. 2010). This is a particularly attractive trait for improvement.

2.02.5 Atmospheric CO_2

Atmospheric concentrations of CO_2 continue to rise due to increasing use of fossil fuels, biomass burning, and cement manufacturing. Rising concentrations of atmospheric CO_2 stimulate biomass and yield production of soybean (Allen and Boote 2000; Ainsworth et al. 2002). Elevated CO_2 also reduces plant water use by soybean due to decreased stomatal conductance and transpiration (Allen and Boote 2000; Booker et al. 2004; Bernacchi et al. 2007). Net photosynthesis in soybean is increased by 23–39% at twice-ambient CO_2 (Allen and Boote 2000; Ainsworth et al. 2002). A decline in photosynthesis occurs in some plants grown at elevated CO_2 (acclimation), accompanied by a decrease in Rubisco and nitrogen concentration. This does not occur in soybean, probably because nitrogen supply keeps up with increased carbon assimilation via stimulated nitrogen fixation (Allen and Boote 2000). Photosynthetic and production WUE were both increased by elevated CO_2 (Allen et al. 1994; Allen and Boote 2000; Booker et al. 2004). Gene expression studies with soybean treated with elevated CO_2 revealed increased transcription of genes involved in carbohydrate metabolism, which was suggested to provide increased energy and biochemical precursors for leaf expansion and growth (Ainsworth et al. 2006).

Increasing CO_2 from a concentrations of 330–660 ppm increased soybean seed yield by about 32% on average based on data from a large number and variety of experiments (Allen and Boote 2000). Soybean yield was increased by 17% with a CO_2 increase from 380 to 550 ppm in a free-air experiment (Long et al. 2005). Crop model projections for soybean production in Argentina based on GCM GISS modeled climate conditions for 2050 with an atmospheric CO_2 concentration of 550 ppm indicated an increase of 20–30% compared with 1971–94 (Magrin et al. 1997). Higher temperatures and CO_2 concentration enhanced grain production, particularly in the cooler southern region. For the Southeastern United States, a crop model coupled with climate scenarios projected a 6–14% increase in soybean yields with warming, irrigation and elevated CO_2, with the negative influence of 2 °C higher temperature counteracted by a CO_2 increase from 330–550 ppm (Alexandrov and Hoogenboom 2000). Simulations of soybean yields in Georgia, USA, showed increases with elevated CO_2 under both irrigated and rainfed conditions. Nationally, soybean yields are projected to increase by about 10% with a mean temperature increase of 1 °C and CO_2 at 560 ppm compared with 365 ppm, but yields decline by 5–10% with a temperature increase of 2.5 °C (Thomson et al. 2005).

Limitations to the projections included uncertainty in climate predictions of temperature and precipitation, changes in the frequency of extreme weather events and frequency of drought, management adaptation and technological improvements, and indirect impact of weeds, diseases, and insect pests due to climate changes (Alexandrov and Hoogenboom 2000; Thomson et al. 2005), such that these projections should be considered, at most, a subset of the range of possible climatic conditions in the coming decades. Variability in projected soybean yields was most strongly affected by variation in precipitation projected by the climate models (Thomson et al. 2005).

In some legumes, such as soybean and peanut, elevated CO_2 enhances symbiotic nitrogen fixation (Serraj and Sinclair 2003; Rogers et al. 2006; Tu et al. 2009). This is likely related to increased availability of photosynthate from increased photosynthesis that stimulates growth and demand for nitrogen along with increased carbon allocation below ground (Rogers et al. 2006). Rogers et al. (Rogers et al. 2006) found that CO_2 enrichment ameliorated the early season decline in plant nitrogen concentration in soybean, indicating improved nitrogen assimilation and probably nitrogen fixation during reproductive growth. Small differences in plant nitrogen concentration at harvest and decreased $\delta^{15}N$ values showed that elevated CO_2 enhanced nitrogen acquisition from the soil and through symbiotic nitrogen fixation in peanut (Tu et al. 2009).

There are findings from open-top chamber and free-air systems that soil organic matter (SOM) turnover appears to be accelerated under elevated CO_2 (Peralta and Wander 2008; Moran and Jastrow 2010; Cheng et al. 2011). In a 6-year no-till soybean–wheat study, soil microbial activity, biomass, community composition, and nitrogen mineralization were increased by elevated CO_2 (Cheng et al. 2011). Accelerated SOM turnover rates may have long-term implications for soils productive and C storage potential and calls for deeper investigation into C and N dynamics in highly productive row crop systems.

2.02.6 Tropospheric Ozone

Ozone is formed in the lower atmosphere (troposphere) when its precursors (nitrogen oxides and carbon monoxide) generated mainly from fossil fuel combustion react with volatile organic compounds and oxygen in the presence of sunlight. Natural vegetation is also a source of volatile organic compounds and has significant influences on regional atmospheric chemistry. Ozone is a greenhouse gas. It contributes the third largest increase in direct radiative forcing (~12%) and first after the long-lived species (Prather et al. 2001). It also modifies the lifetimes of other greenhouse gases such as methane through its reactions with OH. Activities in the energy-generating and transportation sectors generate the majority of ozone precursors although off-road vehicles, methane emissions, large fires, and industrial processes contribute to surface-level ozone as well. Current global tropospheric ozone concentration is about 34 DU, although its budget is difficult to derive owing to its high chemical reactivity and rapid turnover (Prather et al. 2001). Mean surface ozone ranges from 40 to 50 ppb over large parts of North America, southern Europe, and Asia (Dentener et al. 2006). Ozone is not limited to urban areas. Ozone and its precursors can be transported hundreds of kilometers into rural areas where agricultural activities occur and native and managed forests exist, including culturally important Class I Wilderness Areas. Efforts to reduce pollution emissions have mostly succeeded in lowering peak concentrations, but mean ozone levels in many areas remain high enough to impact crops and forests (Booker et al. 2009).

There is concern that future reductions in local ozone formation, due to stricter air quality standards, will be offset by rising background levels as global industrialization increases. There is evidence that ozone, along with it precursors, is increasingly transported from Asia over the Pacific Ocean to North America. Models (A1FI and A2 IPCC SRES scenarios) project increasing ozone precursor emissions (mainly NO_x and CH_4) and predict tropospheric ozone concentrations of 44 DU and 55 DU by 2050 and 2100, respectively (Prather et al. 2001, 2003). More immediately, by 2030, 'business as usual' SRES scenarios project near-surface ozone increases that range from 9 to 34% (averaging 25%), about 5 (+2 to +7) ppb over the Northern Hemisphere, which would seriously impede ambient air quality standard attainment (Prather et al. 2003). If proposed emission control legislation is implemented worldwide, however, ozone concentrations in 2030 could be stabilized at 2000 levels except in regions (e.g., India, China) with large increases in energy, transportation, and industrial activities (Dentener et al. 2006). Efforts to mitigate climate change are also projected to lower ground-level ozone concentrations and radiative forcing (West et al. 2007). However, climate models suggest that air pollution episodes will occur more frequently during the growing season in regions such as the Midwestern and Northeastern United States due to increases in temperature and changes in atmospheric circulation patterns (Mickley et al. 2004; Dentener et al. 2006).

Many well-executed and reproducible studies indicate that soybean growth and yield are suppressed by ambient ozone levels now occurring in many regions of the United States and worldwide (Morgan et al. 2003; Booker et al. 2009; Cho et al. 2011). Independent verification of soybean yield losses at current ambient ozone concentrations in the Midwestern United States was accomplished using ground and satellite ozone measurements (**Figure 2**) (Fishman et al. 2010). Yield losses on the order of 10% could be estimated through the use of a multiple linear regression model (Fishman et al. 2010). Yield loss trends were consistent with results obtained from open-top chamber experiments and from the open-air exposure experiment conducted in the Midwest (SoyFACE).

Recent advances in understanding plant responses to ozone derive from innovative genomic and proteomic studies (Cho et al. 2011). Following uptake through the stomata in the leaf, ozone interacts with cellular processes to cause inhibition of photosynthesis, growth, and yield. Gene expression and proteomic studies show that detrimental ozone effects are likely caused by a combination of chemical toxicity and plant-mediated responses that either amplify or contain injury.

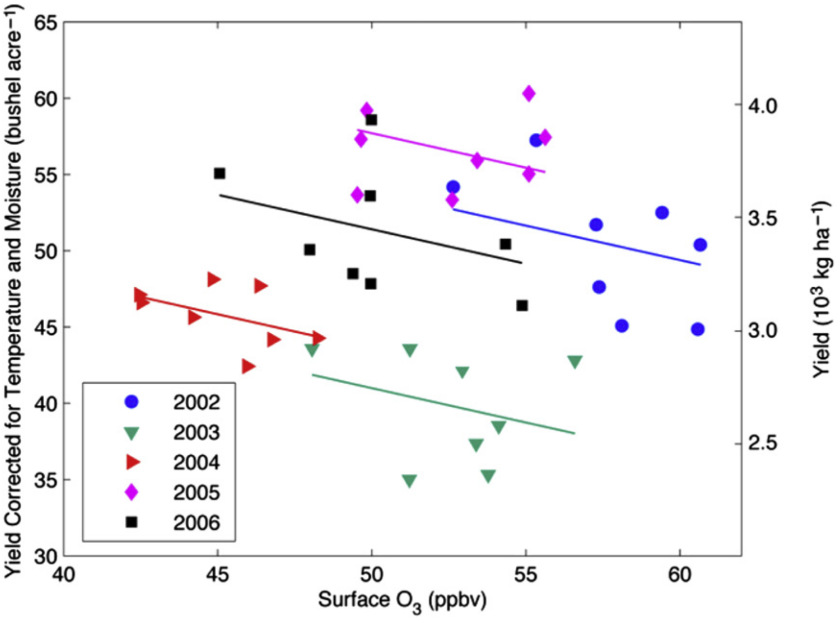

Figure 2 The relationship between soybean seed yield and surface ozone over the southern region of Illinois and Indiana, USA (37–40 °N) from 2002 to 2006 (Fishman et al. 2010). Yield data were obtained from the USDA National Agricultural Statistical Service and summer ozone data were obtained from U.S. Environmental Protection Agency monitoring stations. All data were provided and compiled on a county-wide basis. An investigation of widespread ozone damage to the soybean crop in the upper Midwest determined from ground-based and satellite measurements. Atmospheric Environment 44:2248–2256.

Expression of genes and proteins involved in photosynthesis is suppressed while carbohydrate catabolism, oxidative signaling, and antioxidant and defense pathways are stimulated by ozone (Ahsan et al. 2010; Cho et al. 2011). The responses are hypothesized, due in part to a need for energy and reducing power to detoxify and repair damage caused by oxidative molecules (Ahsan et al. 2010). Similarities between responses to ozone and programmed responses to biotic pathogens have led to conceptual breakthroughs in understanding ozone impacts (Sandermann Jr. et al. 1998).

At the agroecosystem level, ozone effects on soil carbon and nitrogen dynamics have not been well characterized. Changes in below ground processes are hypothesized to result mainly from ozone effects on plant carbon allocation and biomass production, which are generally reduced by ozone, especially in roots (Andersen 2003). In a 6-year no-till soybean–wheat study conducted in open-top field chambers, there was no effect of ozone on soil microbial activity, biomass, community composition, or nitrogen mineralization, in contrast to elevated CO_2, which increased these processes (Cheng et al. 2011). Plant residue input in the open-top chamber experiment was less in the added ozone treatment, but no effect on soil nitrogen was found (Cheng et al. 2011). In a study at SoyFACE with 20% higher ozone, bulk soil nitrogen and carbon concentrations were 12 and 15% higher, respectively, than in soil from plots exposed to ambient air (Pujol Pereira et al. 2011). It was suggested that decomposition processes may have been slower under elevated ozone due to the lower amount of plant material input. Decreased N_2 fixation with elevated ozone has been observed in soybean, possibly related to decreased carbon availability due to inhibition of photosynthesis (Flagler et al. 1987; Pausch et al. 1996).

There is no evidence that soil carbon and nitrogen dynamics in highly managed agroecosystems are significantly influenced by ambient ozone in the United States, although it is possible that substantial reductions in biomass production due to higher future ozone levels could influence soil nutrient cycling processes. It should be noted, however, that the potential influence of high ambient ozone levels on soil nutrient cycling has not been widely evaluated.

Ozone sensitivity varies widely among soybean cultivars (Heagle 1989; Burkey and Carter 2009; Betzelberger et al. 2010), and breeders may have inadvertently selected for ozone resistance. Crop breeding programs regularly produce higher yielding varieties that, along with improved management and production practices, increase yields. Selection for ozone tolerance may be occurring as a consequence of yield trials in the field, but ozone tolerance is neither evaluated nor selected in current breeding programs. Genetic approaches could be employed to develop new varieties with improved ozone tolerance.

Ozone toxicity in plants is not wholly dependent on ambient ozone concentration. Other factors influence plant responses to ozone, such as vapor pressure deficit, temperature, soil water content, $[CO_2]$, diurnal and developmental stomatal conductance behavior, plant phenology, and differential cultivar sensitivities to ozone. There is good evidence, for example, that ambient ozone concentration and air temperature are positively correlated. Further research on how climate conditions affect plant responses to ozone is needed.

2.02.7 Climate Factor Interactions and Yield

Analyses of historical temperature–yield relationships suggest that warming would offset some of the yield gains from technological advances, rising CO_2, and other non-climatic factors (Lobell and Field 2007). Increases in atmospheric CO_2 also tend to ameliorate ozone injury in a number of crops, including soybean (Figure 3) (Ainsworth and Long 2005; Booker and Fiscus 2005; Fiscus et al. 2005; Booker et al. 2009). The converse is also true – ozone offsets elevated CO_2 aerial fertilization effects, depending on the cultivar. Elevated CO_2 and ozone pollution interact to affect crop yields, suggesting that projected benefits of rising CO_2 in the atmosphere are overly optimistic and are based on conceptual models that are too simplistic. It is likely that elevated CO_2 would reduce detrimental effects of ozone on soybean yields, although the interaction becomes less effective as ozone concentrations increase. It is unknown how combinations of elevated CO_2, ozone, and warming would affect soybean yields. Elevated CO_2 will reduce ozone uptake and transpiration, and increases not only WUE and TE, but also the canopy temperature, in addition to the effect of higher air

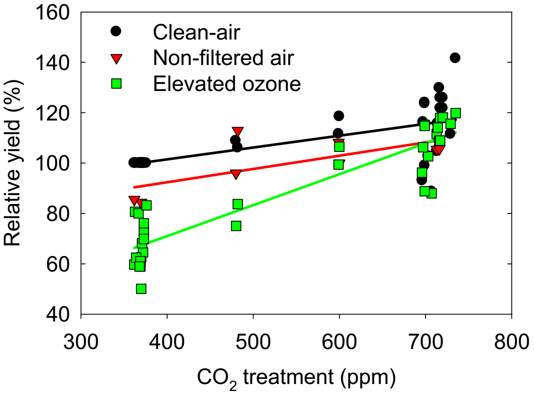

Figure 3 The effects of elevated CO_2 and ozone on relative seed yield of Essex soybean. Plants were treated with a range of CO_2 concentrations in combination with clean-air (charcoal-filtered air), non-filtered air, or elevated ozone in open-top field chambers. Seed yields were expressed relative to yields in the ambient CO_2/clean-air treatments (control). Seasonal ozone concentrations in the clean-air, non-filtered air and added ozone treatments averaged 23, 46 and 74 ppb (12 h average). Data were obtained from 17 experiments conducted over 11 years at Raleigh, NC, USA (Fiscus, E. L., C. D. Reid, J. E. Miller, and A. S. Heagle, 1997: Elevated CO_2 reduces O_3 flux and O_3-induced yield losses in soybeans: possible implications for elevated CO_2 studies. *J. Exp. Bot.*, **48**, 307–313; Heagle, A. S., J. E. Fiscus, and J. E. Miller, 2004: Combined effects of elevated atmospheric carbon dioxide and ozone on soybean whole-plant water use. *Environ. Manag.*, **33**, S355–S362; Booker, F. L., and E. L. Fiscus, 2005: The role of ozone flux and antioxidants in the suppression of ozone injury by elevated CO_2 in soybean. *J. Exp. Bot.*, **56**, 2139–2151; Booker, F. L., J. E. Miller, E. L. Fiscus, W. A. Pursley, and L. A. Stefanski, 2005: Comparative responses of container- versus ground-grown soybean to elevated CO_2 and O_3. *Crop Sci.*, **45**, 883–895; Fiscus, E. L., F. L. Booker, J.-J. B. Dubois, T. W. Rufty, J. W. Burton, and W. A. Pursley, 2007: Carbon dioxide enhancement effects in container- versus ground-grown soybean at equal planting densities. *Crop Sci.*, **47**, 2486–2494).

temperature and possibly vapor pressure deficit. This will tend to increase transpiration, respiration, and other physiological processes, including developmental rate. Both elevated CO_2 and water stress increased leaf temperatures and leaf-to-air vapor deficit of soybean (Allen et al. 1994).

Land-use changes associated with soybean production are generally correlated with changes in precipitation (Thomson et al. 2005). In Brazil, there is concern that deforestation is indirectly related to increasing soybean cultivation as agriculture encroaches on pastures, displacing them to the frontier and encouraging deforestation (Barona et al. 2010; Arima et al. 2011).

2.02.8 Conclusion

Drought is the primary climate change threat to crops, while increasing temperature is secondary (Dai 2011; Sinclair 2011). There has been substantial progress in interpreting the effects of water stress, elevated CO_2 and ozone on plants, and the mechanisms by which those effects are mediated. However, there is much to be done in a practical sense before that information can be translated into useful products. A current need is to identify genetic sources of adaptive traits that breeders can use to improve soybean. New crop cultivars, many of which are genetically modified, are being placed into production without specific consideration of their sensitivity to rising CO_2 or air pollution. Crop breeding programs need to incorporate a selection of traits for improved plant tolerance to abiotic stress in order to maintain and increase crop yields and nutritive quality. With rising CO_2 and temperatures, soybean yields would likely increase, but become more variable year to year (Sinclair and Rawlins 1993). However, with drought, soybean yield would decline strongly, which leads to supply and price volatility, which is a significant risk to the marketplace (Sinclair and Rawlins 1993).

Application of genomics has potential to improve stress tolerance in soybean. Screening modern cultivars and/or germplasm used in current breeding programs is the current state of the science, but will be limited to optimizing for tolerance within a fairly narrow portion of the genetic base. Greater long-term impact may be derived from initially screening a broader set of germplasm to identify genotypes with greater or more diverse sources of tolerance to various abiotic stresses such as drought or ozone (Carter et al. 2004; Burkey and Carter 2009). Breeding for ozone tolerance, for example, may enhance plant tolerance to other abiotic stresses, or vice versa, so it may be useful to screen for ozone tolerance within germplasm that is developed to withstand other stress factors, and the converse may be true as well (Burkey and Carter 2009).

2.03.1 Introduction

Food security is a critical issue in the developing world. For about three billion people, more than half the world's population, rice is staple food. In Asia as a whole, much of the population consumes rice in every meal. In many countries, rice accounts for more than 70% of human caloric intake. Rice is rich in nutrients and contains a number of vitamins and minerals. It is an excellent source of complex carbohydrates, the best source of energy. Rice is a member of the grass family (Gramineae) and belongs to the genus *Oryza* under tribe Oryzeae. The wild species are widely distributed in the humid tropics and subtropics of Africa, Asia, Central and South America, and Australia (Chang 1985). Of the two cultivated species, African rice (*Oryza glaberrima* Steud.) is confined to West Africa, whereas common or Asian rice (*Oryza sativa* L.) is now commercially grown in 112 countries, covering all continents. India is the second largest producer of rice in the world after China with total production of 143 million tonnes (**Figure 1**) accounting for 21% of total rice production (FAO2010). Rice in India is grown on 43 million ha in a diverse set of agro-environments varying in seasons, temperatures, rainfall, soil types, hydrology, varieties, and input management. It is the staple food for a large majority of population and constitutes 43% of the total food (cereal and pulse grain) production. The nutritional composition of rice is given in **Table 1.**

In recent years, with the growing recognition of the possibility of changes to regional and local temperatures and precipitation, an increasing emphasis on world food security, in general, and its regional impacts, in particular, has come to the forefront of the scientific community. There is now clear evidence for an observed increase in global annual average temperatures. The total greenhouse gas (GHG) emissions due to anthropogenic activities have grown substantially with an increase of 70% between 1970 and 2004. Out of all the GHGs, carbon dioxide (CO_2) is the most important greenhouse gas which recorded 80% increase from 21 to 38 (Gt) between 1970 and 2004 which constitutes 77% of total CHG emissions in 2004. Similarly, the growth rate of CO_2-eq emissions was much

higher between 1995 and 2004 (0.92 Gt CO_2-eq/year) than during 1970–94 (0.43 Gt CO_2-eq/year). India faces major challenges to increase its food production to the tune of 300 million tons in order to feed its ever growing population, which is likely to reach 1.30 billion by the year 2020 (Figure 2). To meet the demand for food from this increased population, the country's farmers need to produce 50% more grain by 2020 (Paroda and Kumar 2000). The problem has became acute because urbanization and industrialization have rapidly dwindled the per capita availability of arable land from 0.48 ha in 1950 to 0.15 ha by 2000 and is likely to further reduce to 0.08 ha by 2020 (FAO, 2010). Crop growth, development, water use, and yield under normal conditions are largely determined by weather during the growing season. Even with minor deviations from the average weather patterns, the efficiency of precisely applied inputs and food production is seriously impaired. It is, therefore, important to quantify the possible impact of climate change on rice yields.

2.03.2 Constraints in Rice Production

Rice is grown in irrigated as well as rainfed ecosystem posing several limitations to the yield. The productivity of rainfed ecosystem is significantly lower than the irrigated ecosystem, because of irregularity in rainfall in both amount and distribution during the crop growing period. The current climate is causing an increasing high intensity rainfall and long dry spell, which is a serious threat to rice production as it requires sufficient water throughout its growing period. Though the rice productivity of irrigated ecosystem is higher than the rainfed, there exist large gaps between actual farmers' yield and potential yield (Table 2). For minimizing the yield gap, it requires the concerted efforts, from governments' rice policies to ensuring appropriate land leveling, efficient water control, appropriate inputs (improved seeds, fertilizers, pesticides) supplies, credit provision, and effective institutional supports (research, extension, marketing, incentive rice price). The major constraints of rice production system are discussed as follows.

Table 2 Yield gaps of irrigated rice in selected countries, FAO 2004

Country	*Actual farm yield (tonnes/ha)*	*Potential farm yield (tonnes/ha)*	*Yield Gap (tonnes/ha)*
India (northern zone)	4.0	6.8	2.8
Korea, Republic of	7.0	7.6	0.6
Philippines	5.5	7.5	2.0
Viet nam	6.5	8.5	2.0
Egypt	8.5	10.4	2.1
Madagascar	4.1	6.0	2.1
Italy	6.0	9.0	3.0
Brazil	5.5	8.5	3.0

2.03.2.1 Abiotic Stress

Crop growth, development, and yield are dependent on weather parameters in season. Any minor deviations in the weather parameters can hamper the growth and development leading to reduction in the yield. Climate impacts on rainfall and runoff affect the availability of water for irrigation in many regions and countries in the world. A decline in rainfall along with an increase in temperature, for example, would increase crop water requirements, due to high evapotranspiration, while less rainfall would increase crop net irrigation water requirements. As a result, the already existing water scarcity problem would be exacerbated in many regions and countries, and affect food production.

Rice plant growth can be divided into three agronomic stages of development:

1. Vegetative (germination to panicle initiation): This phase involves tillering, increase in plant growth parameters, and leaf emergence.
2. Reproductive (panicle initiation to heading): This stage is characterized by panicle initiation, flag leaf, heading, and flowering.
3. Grain filling and ripening or maturation.

Light intensity and temperature are very important during this interval since 60% or more of the carbohydrates used in grain filling are photosynthesized during this time interval. All stages of development are sensitive to temperature. It is the main factor controlling the rate of crop development (Table 3). Development generally accelerates as temperature increases which is linearly correlated up to critical temperature. In experiments under controlled conditions from 25 to 35 °C, mean grain weight declined 16% for each 5 °C increase in temperature (Asana and Williams 1965). For every 1 °C rise in temperature, there is a depression in grain yield by 8–10%, mediated through 5–6% fewer grains and 3–4% smaller grain weight.

2.03.2.1.1 Impact of Elevated CO_2 and Temperature

The different rice varieties have different period of growth cycles. *O. glaberrima* has the ability to anthese during early morning and escape high temperatures during the later hours of the day (Yoshida 1981; Prasad et al. 2006). On the other hand, *O. sativa* spp. flower later during the day (Prasad et al. 2006) experiencing high day temperatures, which may lead to the spikelet sterility. The early morning flowering advantage of *O. glaberrima* has been exploited in interspecific crosses between *O. glaberrima* and *O. sativa* to advance peak flowering toward early hours.

High temperatures (35 °C) during anthesis and microsporogenesis resulted in 71 and 34% decline in the spikelet fertility, respectively (Yoshida 1981). Several long- and short-term CO_2 enrichment studies revealed that doubling the current ambient CO_2 increased leaf photosynthetic rate by 30–70% (Ghilidyal and Natu 2000). The magnitude of this increase depends on rice cultivar, growth stage, and environment. Since one of the major effects of elevated CO_2 on net photosynthesis is suppression of photorespiration, it could be expected that optimum temperature for photosynthesis could shift upwards. The effect of CO_2 enrichment on rice leaf area development is small (Nakagawa et al. 1993; Kim et al. 1996; Ziska et al. 1997), but the canopy photosynthetic response is mainly attributed to responses at the unit leaf area level. Mathauda et al. (2000) showed the effect of temperature increase on rice crops. An increase of temperature decreases the life span, grain yield, maximum leaf area index, biomass, and straw of the rice. Elevated CO_2 increases phenological developmental rate and hence reduces the number of days to heading (Baker et al. 1990; Nakagawa et al. 1993; Kim et al. 1996). Baker et al. (1990) found that elevated CO_2 did not significantly affect the interval between similar growth stages of successive leaves of rice, but the leaf number was reduced due to accelerated phenological development. Factors that have been known to influence the response of rice plant growth to elevated CO_2 include phenological stage, cultivar, season, air temperature, and nutrient supply. However, our understanding of these factors still cannot satisfactorily explain the large variations of results obtained in different high CO_2 studies. The reported yield reductions, under increased night temperature cannot be fully explained by effects on respiration. Other mechanisms also may contribute to the observed yield reduction, such as differential effects of night versus day temperature on tillering, leaf area expansion, stem elongation, grain filling, and crop phenological development. Greater fundamental understanding is needed regarding the effects of night temperature on physiological processes governing crop growth and yield development (Peng et al. 2004).

Lobell (2007) conducted a study to evaluate the changes in the diurnal temperature range, which affect crop yield. Data on national crop yields for 1961–2002 in the 10 leading producers of wheat, rice, and maize were combined with datasets on climate and crop locations to evaluate the empirical

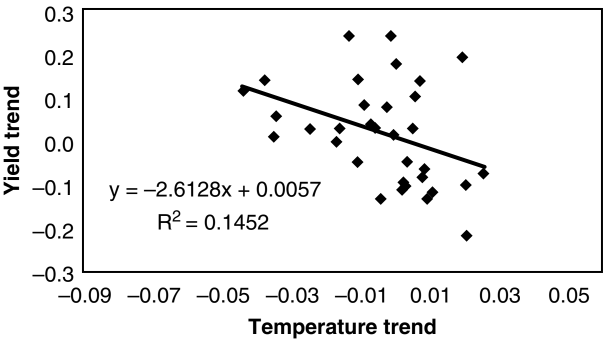

Figure 3 Temperature and yield trend over major rice growing sites in India

relationships between average temperatures (T_{avg}), diurnal temperature range (DTR), and crop yields. In several rice and maize growing regions, including the two major nations for each crop, there was a clear negative response of yields to increased DTR. This finding reflects a nonlinear response of yields to temperature, which likely results from greater water and heat stress during hot days. In many other cases, the effects of DTR were not statistically significant, in part because of the correlations of DTR with other climate variables, and the relatively short length of the time series resulting in wide confidence intervals for the estimates.

To evaluate whether a subset of future plausible changes in DTR are relevant to crop impact assessments, yield responses to projected changes in T_{avg} and DTR by the year 2046–65 from 11 climate models were estimated. The mean of climate model projections was increased in DTR in most seasons and locations where wheat is grown, mixed projections for maize, and a general decrease in DTR for rice. The estimated impacts of DTR changes on yields were generally small (<5% change in yields) relative to the consistently negative impact of warming of T_{avg}. However, DTR changes did significantly affect yield responses in several cases, such as in reducing US maize yields and increasing India rice yields. Because DTR projections tend to be positively correlated with T_{avg}, estimates of yield changes for extreme warming were particularly affected by including DTR (up to 10%). In India also, an increasing trend of daily average temperature resulted a decreasing trend in rice grain yield as estimated using past years weather data (Figure 3).

Many of these impact studies were aimed at assessing crop development shifts and yield variations under changes in climate conditions. These analyses showed that increasing temperatures generally shortened the growing period of commercial crops (e.g., Bindi et al. 1996), resulting in a shorter time for biomass accumulation. On the other hand, changes in yields were not homogeneous and dependent on crop phenology (e.g., summer and winter crops), crop type (e.g., C3 and C4 plants), or environmental conditions (water and nutrient availability) (Ainsworth and Long 2005). Crop modeling approaches are being used to evaluate the effect of elevated CO_2 and temperature on change in yield under projected climate change scenarios. Results of similar study conducted by Matthews et al. (1997) in Asian countries are given in Table 4.

Table 4 Mean predicted changes (%) in potential yields under the 'fixed' temperature and CO_2 scenarios using ORYZA1 and SIMRIW crop models.

Matthews, R . B ., M. J. Kropff, T. Horie, and D. Bachelet, 1997: Simulating the impact of climate change on rice production in Asia and evaluating options for adaptation. *Agric. Syst.*, **54,** (3), 399–425.

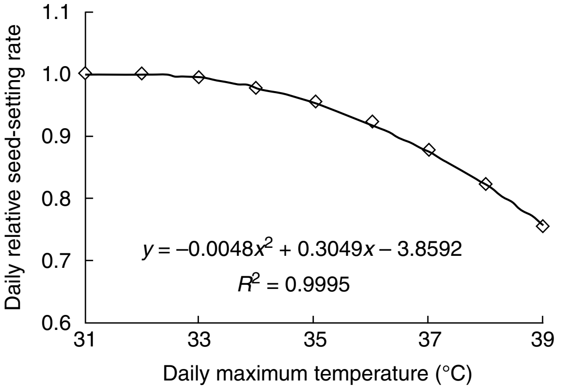

Figure 4 Relationship between daily maximum temperature and relative seed-setting rate under natural change pattern of temperature (Chun-Lin, S. H. I., J. I. N. Zhi-Qing, J.-C. Zheng, and R.-S. Tang, 2008: Effect of high temperature at meiosis stage on seed-setting rateinrice, *Acta Agron. Sin*, **34** (4), 627–631.)

Heading and meiotic stages are the most important stages of rice crop and both these stages are very sensitive to temperature. Temperature above 35 °C at the above two growth stages is very harmful for grain development of rice crop. High temperature results in spikelet sterility, which further results in relative seed-setting rate and grain yield (Sataka and Yoshida 1978; Matsui et al. 2001; Prasad et al. 2006). Chun-Lin et al. (2008) evaluated the effect of high temperature on rice yield quantitatively by conducting experiments on two rice cultivars. They conducted the experiment with a controlled (natural) temperature and with 31, 33, 35, 37, 39, and 41 °C at different meiotic stages of rice. Effect on the seed-setting rates was observed on both cultivars when the temperature was lower than 33 °C. But the temperature and its duration had a negative impact on seed-setting rate and the decrease rate follows a quadratic equation (Figure 4).

Unique field experiments indicated that the effects of elevated CO_2 and temperature on rice plants could increase methane emissions from rice fields, providing an important feedback to climate change from rice cultivation (Olszyk et al. 1999; Ziska et al. 1997). Methane gas emission from

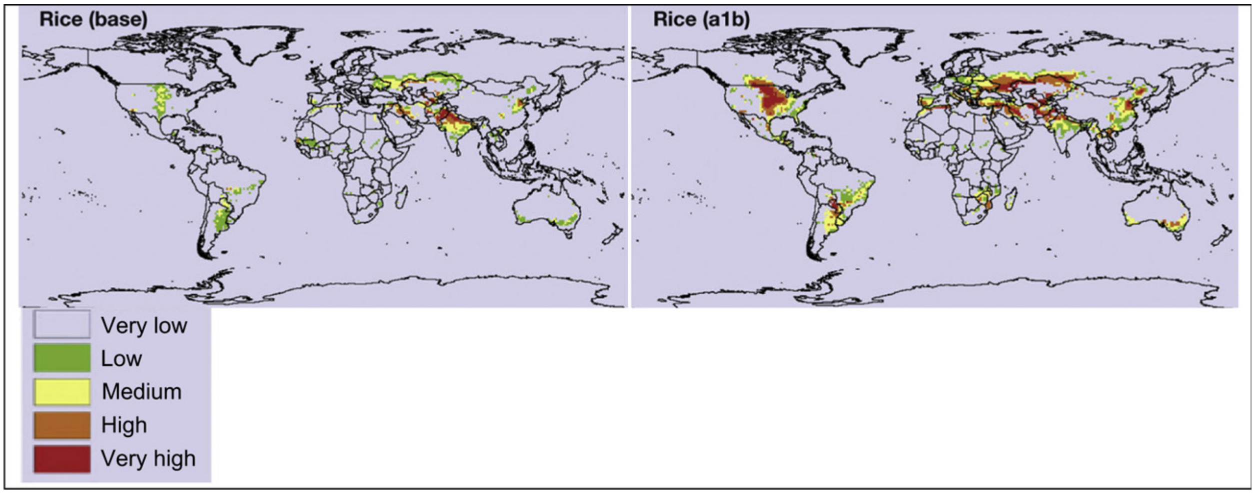

Figure 5 The maximum heat stress intensity within a 30-year simulation in areas suitable for the production of rain-fed wetland rice for the baseline climate (Base, 1971–2000) and the A1B climate change scenario (2071–2100). (Teixeira, E. I., et al., Global hot-spots of heat stress on agricultural crops due to climate change. Agric. Forest Meteorol. (2011), doi:10.1016/j.agrformet.2011.09.002 (article in press).)

rice fields in different countries is given in Table 5 (Leip and Bocchi, 2007). Elevated CO_2 or in combination with elevated temperature produced a large increase in methane emissions from rice fields compared to current conditions; primarily due to a large increase in below ground biomass. In contrast, elevated temperature alone tended to decrease methane emissions from rice fields. The magnitude of these changes in methane emissions from rice fields were not predicted by current plant growth simulation models (Olszyk et al. 1999).

Global hot spots of crop heat stress overlap with major agricultural regions such as Eastern China, the Northern United States, Southwestern Russian Federation, and Southern Canada in one plausible Intergovernmental Panel on Climate Change (IPCC) scenario (Figure 5). This indicates that agricultural production in temperate countries likely suffers from substantial production losses from climate extending the findings of previous studies that impacts would mainly occur in subtropical and tropical regions (IPCC 2007a; Fischer et al. 2002, 2005).

It is predicted that CO_2 concentration will reach twice the present level in the next century (Houghton et al. 1990). Rising CO_2 concentrations can stimulate photosynthesis and growth of a wide range of C3 plants. The microclimate, nutrient conditions, and limited usable area in the chambers can change the plant responses to elevated CO_2. The predictions obtained from laboratory experiments should be evaluated under field conditions. In addition to the ecophysiological processes of plants examined in the laboratory experiments, elevated CO_2 could change various environmental conditions, including the carbon cycle and nitrogen metabolism. Increasing carbon input to the soil through increased root growth, root exudation, altered litter quality, and increased soil water use under elevated CO_2 can all affect soil nitrogen transformations and carbon dynamics. Along with CO_2 another important factor is O_3. Ground level O_3 concentrations have been increasing worldwide (and are expected to continue to increase) due to increased emissions of pollutants that react to produce O_3 (Vingarzan 2004). High atmospheric concentrations of ozone can cause damage to leaves and decreased plant growth and photosynthesis (Feng et al. 2008; Morgan et al. 2003). The primary location of O_3 injury to plants is the internal tissues of leaves. Decreased openness of stomata under elevated CO_2 can therefore decrease exposure of sensitive tissues to ozone. Elevated CO_2 substantially decreases the negative effects of high ozone on photosynthesis, growth, and seed yield in both soybeans and rice. There is little information concerning the respiratory behavior of the rice crop throughout its growth cycle. Carbon losses due to growth and maintenance

Table 6 Number of grains per m^2 (NOG), percentage of filled grains (PFG), individual grain weight (GRW), seed yield (Y), and harvest index (HI) of rice grown under elevated (ca 570 μmol mol^{-1}) and ambient CO_2 (ca 370 μmol mol^{-1}) open top chambers and in open field conditions in Maha (Jan–Mar) and Yala (May–Aug) seasons of 2001

Abeywardena, 2006: Physiology of yield determination of rice under elevated carbon dioxide at high temperatures in a subhumid tropical climate. *Field Crops Res.*, **96,** 336–347.

respiration typically amount to 40–60% of the total carbon fixed by a crop (Pritchard and Amthor 2005). In tropical areas, this percentage may even be higher. Early in the growing season, growth respiration dominates. At later stages, maintenance respiration may account for 50% of the total respiration loss and it is much affected by environmental conditions within the crop canopy. Since growth respiration is proportional to crop biomass, it can only be reduced by lowering the growth rate or by changing the biochemical composition of the phytomass produced. In contrast, maintenance respiration can be altered through genetic improvement and management. Some evidence of genetic variation in maintenance respiration exists for other crops (Winzeler et al. 1988; Earl and Tollenaar 1998) and there have also been attempts to select more respiration efficient germplasm (Wilson and Jones 1982).

Rice yield was found to be increased with increase in CO_2 concentration (Baker et al. 1990) from experiments conducted by the International Rice Research Institute (IRRI). The experiment conducted by Baker et al. revealed that 28 °C is the optimum temperature for rice growth. At the optimum temperature level, the increase in CO_2 concentration increased the grain yield through an increase in the number of filled grains per panicle and an increase in individual seed mass of about 1–2 mg per seed. Along with that, the CO_2 enrichment also increased above ground biomass and harvest index at the optimum temperature level.

An experiment was conducted on rice growth with elevated CO_2 concentration. Rice was grown over two seasons in a subhumid tropical climate in Sri Lanka, at elevated CO_2 concentration, and ambient CO_2 in open top chambers with open field plots to estimate chamber effects. The CO_2 within the chambers was maintained around target concentration by a computer-based real time data acquisition and control system. Rice under elevated CO_2 showed significantly greater (20 and 11% in the two seasons) RUE relative to the ambient CO_2. The radiation use efficiency under elevated CO_2 did not show a reduction during the post-heading period. Consequently, the total biomass at harvest was 23–37% greater under elevated CO_2. Observations were that the number of grains initiated and percentage of grains filled were significantly greater under elevated CO_2, resulting in final seed yields being 24 and 39% greater than ambient as shown in Table 6 (De Costa et al. 2006).

Yang et al. (2009) using free air CO_2 enrichment (FACE), measured seasonal changes in growth and nitrogen uptake of an inter-sub specific hybrid rice cultivar, *liangyoupeijiu* grown under two levels of CO_2 (ambient and elevated 200 μmol mol^{-1}) and two levels of N fertilization. The results showed FACE increased crop growth rate in the periods from transplanting to panicle initiation (PI), PI to heading and heading to maturity, which was mainly attributed to an increase in green leaf area index rather than the greater net assimilation rate. Grain yield increased greatly under FACE as a result of similar contribution by panicle number per unit area, grain number per panicle, and individual grain yield.

Studies of rice responses to CO_2 enrichment have focused on photosynthesis, water relation, phenology, organ formation, dry matter production and distribution, carbon and nitrogen metabolism, as well as grain yield, and its components, but very few studies have been carried out on the effect of elevated CO_2 on grain quality. The Japan FACE study indicated that the milling degree of *Japonica cv.* Akitakomachi with small panicle was significantly lower in elevated (CO_2) conditions with relatively lower nitrogen (N) application (9 g m^{-2}). The decrease of head rice percentage under elevated (CO_2) might attribute to substantial amount of assimilates retained in the alureone layer, which was removed during milling process. The CO_2 induced changes in grain appearance and deterioration in milling quality were closely correlated. The increase in grain chalkiness and decrease in milling suitability of rice under elevated CO_2 indicated softer (easily broken and ground) rice grains harvested under projected high (CO_2), which might affect market value of rice in the future. Amylose content is considered to be the key factor that contributes to the cooking and eating quality of rice. The higher the amylose content the more hardness in cooked grain. Amylose content is expected to increase with higher CO_2 content. Both FACE and chamber experiments indicated that elevated CO_2 significantly decreased protein and nitrogen concentration of rice grains, regardless of cultivar, N or P level applied to plants (Terao et al. 2005; Dong et al. 2002: Yang et al. 2007).

2.03.2.1.2 Water Limitation

The amount of water required to produce 1 kg of rice is 4000–5000 l of water leading to 50% water use efficiency. This can be increased to 80% if drained water is recycled. Although the Asian countries have abundant monsoon, it is expected that Asian countries will suffer from a water shortage by 2025 at the current rate of population and urbanization. Water logging is the main problem, followed by salinity, toxicity, and water pollution. Rice varieties differ greatly in their ability to tolerate aerobic soil and moisture deficit. The greatest ability to grow and produce some grain with chronic moderate water deficit is found in japonica varieties from upland ecosystems such as those found in hilly Southeast Asia and Africa (Mackill et al. 1996). The intrusion of sea water in coastal lands, leading to salt accumulation is a major problem. Water productivity of rice in terms of yield per unit of water evapotranspired ranges from a low of about 0.4 kg rice m^{-3} water evapotranspired to as much as 1.6 kg m^{-3} for wet seeded rice in the Philippines (Tuong 1999). Pollution of water resources, both surface water and groundwater, and of the air by industrial and urban emissions presents increasingly severe problems for rice production near urban and industrial centers. Its mitigation requires large-scale improvements in industrial and urban waste management.

2.03.2.1.3 Land Characteristics

In Asia, the average land holding of farmer is very poor. In addition to that, due to rapid urbanization and industrialization the cultivable land is also used for permanent construction and other purposes. Permanent water logging and rice monoculture have commonly caused microelement deficiencies, especially zinc and sulfur, and toxicities, notably iron. Though rice is adapted to waterlogged conditions because of the well developed aerenchyma that facilitates oxygen diffusion and prevents anoxia in roots, complete submergence can be lethal. Out of 40 million ha in Asia grown under rainfed lowlands, about 15 million ha are frequently damaged by submergence (Huke and Huke 1997). The effect of flash-flooding interacts with growth stage. Germination is highly sensitive to flooding. Zinc is the dominant element responsible for loss of fertility of wetlands followed by sulfur deficiency. Farmers through the application of chemical fertilizers give macronutrients, but neglect the supply of micronutrients. Eventually, the micronutrients become deficient leading to a nutritional imbalance in the soil.

2.03.2.1.4 Economics of Rice Production

Supply of water was the main factor during the green revolution in India. After that, the availability of water and necessary infrastructure for irrigation declined due to less investment. On the average, rice production activities employ 243 people per day per hectare in Bangladesh, 195 people per day per hectare in India, 156 people per day per hectare in Indonesia, and 60–80 people per day per hectare in the more mechanized production systems of the Philippines and Thailand (Pingali et al. 1997). Since 1995, international rice prices have declined markedly (Calpe 2003), while prices of production inputs such as fertilizers, other agrochemicals, labor, fuel, and rice machinery and equipment either increased or at best remained unchanged. This has been one of the major causes of poverty and hardship for many small farmers in developing countries. About 30% of the produce is lost as a result of poor land preparation, planting, harvesting, post-harvest handling, storage, and processing methods. The low level of engineering technology inputs in agriculture has been cited as one of the major constraint hindering the modernization of agriculture and food production including rice.

2.03.2.2 Biotic Stress

It is estimated that diseases and insects cause yield losses of up to 25% annually. With the increased adoption of direct seeding methods, weedy rice (*Oryza* sp.) has become another major weed in rice production. The economic impact of disease results in losses in productivity, the cost of disease management, and the economic penalty paid for having to grow less profitable alternative crops. The classic disease triangle recognizes the role of the physical environment in plant disease, as no virulent pathogen can induce disease on a highly susceptible host if weather conditions are not favorable. Relationships between weather and disease are routinely used for forecasting and managing epidemics and disease. The severity over a number of years can fluctuate according to climatic variation. Some diseases can cause more severe reduction in plant growth under twice ambient compared to ambient CO_2, at least in controlled environments. Among indirect effects, ozone can predispose plants to result in losses greater than by a pathogen alone, while the effect of UVB is inconsistent (Manning and Tiedemann 1995). More aggressive strains of pathogens with broad host range, such as Rhizoctonia, Sclerotinia, Sclerotium, and other necrotrophic pathogens may migrate from agricultural crops to natural plant communities.

2.03.3 Use of Crop Models for Yield Prediction

Crop production is very sensitive to climate with varying effects and with respect to different regions of the World (McCarthy et al. 2001). The IPCC (Third Assessment Report) analysis on climate impacts estimated a general reduction of potential crop yields and decrease in water availability for agriculture and population, in many parts of the developing world.

Crop growth simulation is a complex phenomenon as it involves interaction of soil, plant, weather, and management. These parameters have significant effect on each other and thereby on crop system as a whole. Dynamic crop growth modeling includes these parameters with the mechanisms and processes such as physiological, physicochemical, and meteorological leading to crop growth and yield simulation. The Wageningen group is the oldest working group for developing and applying crop models in agro-ecological research program. This group has developed and analyzed several crop models with the first effort of C.T. de Wit in the 1960s. The most popular and successful crop models of the Wageningen group include BACROS, LINTUL, SUCROS, ORYZA, WOFOST, INTERCOM, etc. (Ittersum et al. 2003). BACROS was the first crop simulation model developed by De Wit and co-workers of Wageningen University, and the DLO Research Institute for Agrobiology and Soil Fertility. This group also evaluated components of the model with the help of especially designed equipment and field experiments. The SUCROS (Simple and Universal Crop Growth Simulator) was the next outcome of the Wageningen group after the BACROS model. The SUCROS model was developed by Van Keulen (1982) and then Van Laar et al. (1997), which further formed the basis of the most popular crop models such as WOFOST, MACROS, and ORYZA. Next to that Spitters and Schapendonk (1990) introduced based LINTUL (Light Interception and Utilization) model for simulation of dry matter accumulation based on the light use efficiency.

MACRO (Modules of an Annual Crop Simulator) simulates the crop growth by emphasizing the biochemical aspect of plant physiology based on the concept of growth limiting factors (de Wit and Penning de Vries 1982; Penning de Vries and van Laar 1982). The input parameters for the growth simulation are solar radiation, maximum and minimum temperatures, precipitation, day length, vapor pressure, and wind speed. MACRO simulates the effect of CO_2 on photosynthesis.

RICEMOD (McMennamy and O'Toole 1983) is a rice growth simulation model which considers photosynthesis as a function of solar radiation, canopy structure, and the ratio of leaf nitrogen weight to area. The main input data for the model are precipitation, pan evaporation, maximum and minimum temperature, day length, and solar radiation. It also considers the soil–water balance relation and assumes optimum levels of nutrients for the crop simulation, but this model does not take into account the effect of natural hazards such as typhoons or pests.

RICESYS (Graf et al. 1990a,b) is a demographic model for rice growth and development. The main input parameters are temperature and solar radiation. This is the model which analyzes the crop–pest interactions and also provides a useful tool for integrated pest management studies.

INTERCOM is another crop model of the Wageningen group, which simulates the effects of pests and diseases. This model considers the crop–weed competition from the partitioning of the growth-defining (light) or limiting (water and nutrients) resources over the competing species and the efficiency with which each species uses the resources to simulate the crop growth and helps to make a decision for the use of pesticides (Kropff and Van Laar 1993).

The ORYZA1 was developed by Kropff et al. of the Wageningen group in the year 1994. The main parameters of this crop simulation model are light, temperature, and other factors, which affect the phenological, morphological, and physiological processes of the crop. The inputs for the model are latitude, daily weather data (global radiation, maximum and minimum temperature), and seeding date. It simulates the daily dry matter production and the rate of phenological development of the crop from these inputs and integrates growth rates over time to calculate dry matter production throughout the growing season.

Hoogenboom et al. (1994) developed a Decision Support System for Agrotechnology Transfer (DSSAT), which integrates various crop simulation models for grains, legumes, cereals, vegetables, and oilseed crops with weather, soil, and experimental databases. It includes various analysis programmes to apply the crop models for decision making pertaining to short and long practical and strategic planning. Under the framework of the DSSAT v3.5 CERES Model is designed to simulate crop growth and development of different crops, which simulates the yield for different soil and nitrogen content conditions, for alternative technology, and for new growing sites. The weather inputs for this model are daily solar radiation, maximum and minimum temperature, and precipitation. It can simulate the impact of diseases on rice yield. The CERES rice model considers photosynthesis as the function of leaf area index and expresses in terms of daily biomass production. The phenological growth and development in the CERES models are mostly cultivar-specific and the model simulates the growth and development stages by the genetic coefficients, which are determined by the photoperiod, thermal time, temperature response, and dry matter partitioning.

The World Food Study (WOFOST) model (Supit et al. 1994) is a one-dimensional, mechanistic, and site-specific crop model for wheat, grain maize, barley, rice, sugar beet, potato, field bean, soybean, oilseed rape, and sunflower. This crop model basically evaluates the crop yield and variability for different climate scenarios and can also be used to estimate crop production, indicate yield variability, evaluate effects of climate change or soil fertility changes, and determine limiting biophysical factors. Weather and soil data are the main inputs for this model, which include rainfall, temperature, wind speed, global radiation, air humidity, soil moisture content at various suction levels, and data on saturated and unsaturated water flow. WOFOST simulates the daily growth of a specific crop based on the light interception and CO_2 assimilation as the growth driving processes and crop phenological development as the growth controlling process of that crop.

CropSyst is basically a process based, multi-year, multi-crop, daily time step cropping system simulation model (Stockle and Nelson 1999; Stockle et al. 2003). This model simulates the soil water budget, soil–plant nitrogen budget, crop growth and development, residue production and decomposition, and soil erosion. The main model inputs include daily weather data, dates and amounts of products applied for each fertilization and irrigation event, sowing date, hydraulic characteristics of the soil profile, crop parameters, and initial conditions of the soil profile, such as crop residues, water content, mineral nitrogen, and organic matter. The main outputs of the CropSyst model are above ground biomass, leaf area index, root depth, soil water, and nitrogen balance. CropSyst simulates the crop development for the whole canopy, which is a function of thermal time accumulated between a base temperature (Tbase) and a maximum temperature (Tcutoff). CropSyst was developed to simulate the growth and development of potentially all herbaceous crops.

Water Accounting Rice Model (Confalonieri et al. 2006) is crop model software which simulates paddy growth and development based on temperature and radiation data. It also simulates biomass partitioning, floodwater effect on temperature, spikelet sterility, floodwater and chemicals management, and soil hydrology of the crop. WRAM is an integration of four tools, namely (1) Monte Carlo–based sensitivity analysis, (2) automatic calibration (based on simple and genetic evolutions of the simplex optimization method), and (3) the evaluation of model performances. The key concept of this rice growth simulation model is that of radiation use efficiency (RUE), a parameter, which is used to convert intercepted solar radiation into above ground biomass.

2.03.4 Climate Adaptation

Adjustments in the ecological, social, or economic systems are made in response to actual or expected stimuli and their effects or impacts. This term refers to changes in processes, practices, and structures to moderate potential damages or to benefit from opportunities associated with climate change (IPCC 2001). Reactive adaptations are those that occur after the impacts of climate have been experienced, while anticipatory adaptations are pro-active, undertaken before the impacts are fully felt. Planned adaptations are generally anticipatory, but can also be reactive (i.e., adaptations are planned to be implemented once variations in local and regional climate effects are experienced) (Klein and Tol 1997). India is vulnerable to any increase in occurrence of extreme climatic events. Climatic influences can result in a hindrance in development and potential changes in social and environmental conditions. Technology transfer can play a key role in the modernization of processes in addition to government initiatives. Historically, farming systems have adapted to changing economic condition, resources availability, and technology. For adaptation measures, the authors first chose the adjustment of planting dates. Shift in current planting date and induced temperature tolerance to spikelet sterility were found to be suitable adaptation measures for eastern India (Krishnan et al, 2007). Similarly, Swain and Thomus (2010) reported advancement in planting date by 10–30 days and varietal adaptation for reducing the climate change impact on rice production in West Bengal, India. For areas, those are characterized by cold winters from October to April like northern China, the planting date is adjusted by different field experiments. The potential yields were lower under the conventional planting date, due to the effect of increased temperatures on spikelet sterility. Different experiments were conducted to take the advantages of longer growing seasons in temperate climates. The growing period was widened from 120 to about 200 days, from normal planting date of around 1 May, so that both earlier and later sowings become feasible. The wider sowing window allowed the possibility of two rice crops per year. The first crop is sown between the beginning of February and the end of March, with the second being sown in June or July and total annual production was found to be much higher than the single cropping. They also suggested the changes in sowing dates to avoid the high temperatures around flowering that cause spikelet sterility. International Rice Research Institute (IRRI) is developing certain adaptations via plant breeding such as introduction of early morning flowering (EMF) trait to the varieties/screening of varieties which have uniqueness of EMF when atmosphere is cool. Such EMF traits have been observed in *O. minuta* and *O. officinalis* (Sheehy et al. 2007). Introduction of high temperature tolerant gene to a particular variety is also good option for climate change adaptation (Yoshida 1981; Prasad et al. 2006; Jagadish et al 2008).

Sustainable management of soil involves creating a positive C budget, a balanced nutrient–elemental budget, diverse soil faunal and floral activities including those of earthworms and microorganisms, and creating a favorable soil reaction (pH). The soil organic matter is the key element in soil management. The soil organic matter holds significant amount of moisture thereby reducing the runoff. It helps in stabilizing the soil structure. Conservation agriculture and organic agriculture that combine zero or low tillage and permanent soil cover are major adaptation options promoted by FAO for their ability to increase soil organic carbon, reduce mineral fertilizers use, and reduce on farm energy costs.

Risk transfer mechanisms should be included in adaptation strategies from the national to the household level. This can include crop insurance or diversified livelihoods such as integrated aquaculture–agriculture systems which allow activities to shift in response to changes in the suitability of land and availability of water to produce food. Economic diversification within sectors reduces the dependency on climate-sensitive resources, particularly for countries that rely on narrow ranges of climate-sensitive economic activities.

2.03.5 Water Management

Wider use of technologies to harvest water and conserve moisture along with higher water use efficiency is necessary. Managing water to prevent erosion, runoff, water logging, and seepage will help in reducing leaching of nutrients. On-farm water management and supplementary irrigation are necessary to avoid drought. Micro-irrigation, especially sub-surface drip irrigation, is a modern innovation to enhance water use efficiency.

Water productivity in continuous flooded rice areas was typically 0.2–0.4 g grain per kg water in India. The water saving irrigation increased water productivity up to a maximum of 1.9 g grain per kg water, but decreases yield. Irrigated rice is also regularly affected by water stress due to in adequate irrigation water supply. Most water management research has been focused on flooded rice, and limited work has been done on intermittent irrigation with returning aerated soil conditions. The major outflows of water from the rice field are evaporation, transpiration, seepage, percolation, and over bund runoff flow. The seepage and percolation account for about 50-80% of the water input (Bouman et al., 2005). The recent introduction of water saving irrigation technique such as reducing the depth of pounding water, system of rice intensification (Krupnik et al., 2012), alternate wetting and drying (Dong et al., 2012; Yao et al., 2012), and keeping the soil just saturated (Yadav et al., 2011a,b)are options to minimize the seepage and percolation loss of water from rice field.

Soil moisture deficit reduces plant height and tiller number. However, reduction in crop growth and yield depends on degree and duration of water deficit and growth stage of crop. (Raamakrishnayya and Murthy 1991). The effects of water stress on photosynthesis, growth, and development are equally or more important than effects on other processes, especially in annual crops. Rice is more susceptible to moisture stress during early seedling and flowering stages than other stages of growth and generally the reproductive stage is more affected than the vegetative stage.

The system of rice intensification (SRI) developed in Madagascar over a 20-year period and synthesized in early

1980s by the late Father Henri de Laulanie, S.J. Experience with SRI method suggests that average rice yields can be about double and water requirement is half to that of conventional cultivation method. The seedlings at the age of 12–14 days and at 20 cm × 20 cm spacing are transplanted. Since the soil is kept moist only during the vegetative growth phase and only minimal water is kept during the reproductive phase, SRI results in water savings to an extent of 35–40% compared to the conventional method. This method has a fair number of advantages, namely increased tillering, profused root growth, reduced seeding, and fertilizer requirement. However, the success of this method depends upon the water management and accuracy in transplanting.

Glossary

Chilling requirement The minimum amount of cold temperatures needed for a plant to break winter dormancy and resume growth in the spring.

Dormancy A period of reduced plant activity and growth.

Downscaling The process of adding information at scales smaller than the original spatial resolution or temporal aggregation period.

Fall hardening The gradual process by which a plant becomes tolerant of freezing temperatures.

Growing degree days (GDDs) A measure of heat accumulation, calculated as the difference between the daily mean temperature and a specified base temperature. GDDs are frequently used in agriculture to estimate planting times and approximate dates of crop development stages.

Perennial crops Agricultural commodities with life spans of two or more years.

Phenology The growth stages of a plant.

Poikilothermic Organisms whose growth and development is primarily temperature dependent.

Veraison The onset of ripening.

2.04.1 Introduction

Perennial crops, including the commercial production of fruits and nuts, play important dietary and economic roles at local, regional, national, and international scales. The vulnerability of these commodities to climate has not been as widely studied as compared to annual crops, in spite of their greater relative exposure to fluctuating weather conditions due to their perennial nature. In contrast to many annual crops, the spatial extent of perennial crops across the landscape is relatively limited. Rather, perennial crop production is frequently constrained to areas with unique local or regional climates that are often influenced by topographic position, proximity to water bodies, or the presence of mesoscale atmospheric circulations and weather conditions such as frequent fog that modify the local climate. This limited spatial extent of production regions contributes to the climate vulnerability of perennial crop production. Furthermore, orchards require substantial initial investment and the typical lifetime is on the order of 20–30 years, limiting adaptation options and the time scales at which adaptations can be implemented.

Perennial crops present numerous challenges for climate impact and vulnerability assessments. As summarized by Lobell and Field (2011), multiple critical physiological stages must be considered, process-based crop models remain largely unavailable or poorly developed for perennial crops, and the slow growth of perennials makes experimental warming trials less feasible than for annual crops. Also, as pointed out by White et al. (2006), climate assessments for perennial crops must have a fine spatial resolution to resolve subregional scale climate–crop relationships. In spite of these constraints and challenges, a substantial body of literature has evolved on climate impacts on perennial crops that covers multiple production areas worldwide. Based on the frequency of published articles, the fruit crops most investigated are wine grapes, apple, cherry, citrus, peach, and apricot. Numerous other fruit commodities have also been studied including kiwi, mango, pear, pineapple, plum, and strawberry. Almonds and walnuts are the two most widely investigated nut tree commodities.

This chapter reviews prior research examining the impacts of climate on perennial crops. The goals are to (1) highlight vulnerable growth stages and industry components, (2) describe the common methods and analytical techniques used to investigate climate impacts on perennial crops, (3) summarize, based on published literature, the current understanding of temporal trends in freeze risk, heat stress, and the timing of growth stages, and (4) provide our perspective on existing knowledge gaps and recommendations for future research.

2.04.2 Climate Vulnerability of Perennial Crop Production

In general, perennial trees in temperate and cool subtropical climates lose their leaves and begin a cold hardening stage in early fall before becoming dormant in late fall. In some plants, the cessation of growth during fall is triggered by shorter day length, whereas others respond to colder air temperatures. Buds remain dormant or in the stage of 'rest' due to internal physiological blocks (i.e., inhibitors) that prevent their development even under ideal conditions for growth. These physiological blocks are removed when buds are exposed to chilling temperatures above freezing for some weeks. The chilling requirement is often fulfilled in winter for both high- and low-latitude species. After chilling is completed and buds are no longer in a state of 'rest,' they become 'quiescent' and respond to heat accumulation. Cold temperatures during the quiescent period prevent bud growth, whereas buds become active losing much of their hardiness when the temperature becomes favorable for growth. Perennial crops are particularly vulnerable to cold damage at three distinct stages: (1) in the fall before the tree is adequately hardened, (2) during the winter dormant period when severe cold events can cause injury to woody tissue, and (3) during spring when temperatures slightly below freezing may kill flower buds following the loss of cold hardiness (Raseira and Moore 1987). Although cold damage in fall and winter can cause permanent injuries to perennial trees, they are usually less frequent, and have a smaller effect on year-to-year variability in yield, compared to springtime freeze events.

Production is also influenced by other climate factors, such as the amount of plant available moisture in the soil profile, conditions during pollination, the occurrence of prolonged and/or extreme heat or drought events, and the frequency of hail during the growing season. Additionally, weather conditions, including temperature and humidity, contribute to the risk of insect pests and plant diseases, which also affect orchard and vineyard productivity.

An initial step in a climate assessment for perennial crops is the identification of the critical growth stages and related climate factors for the crop in question (Figure 1). Although

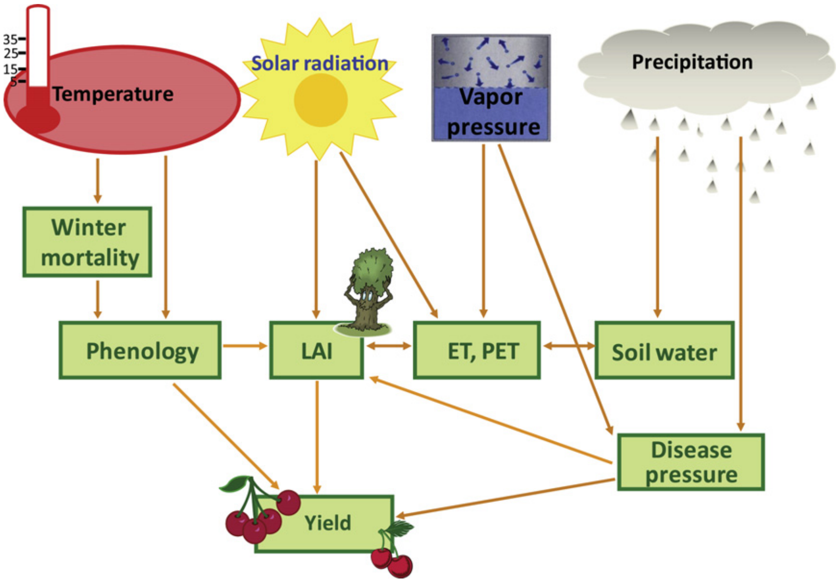

Figure 1 Weather and climate influence a number of aspects of perennial crop development and yield. This cartoon illustrates the potential impacts of four climate variables on sour (tart) cherry production in the Great Lakes region of North America. The cartoon was prepared by Andresen, J. A., J. R. Black, C. Zavalloni, and J. M. Bisanz at Michigan State University for the Pileus Project (http://www.pileus.msu.edu/), and is used here with their permission.

these factors will vary by crop, past studies have highlighted winter chill fulfillment, changes in springtime freeze risk, pollination constraints, heat stress, and enhanced disease and insect pest pressure as particularly contributing to the climate vulnerability of perennial crops.

2.04.2.1 Winter Chill Fulfillment

As noted above, for many commercial perennial tree crops (e.g., apples, cherries, and peaches), a chilling requirement must be met to break winter dormancy and resume growth in the spring (Luedeling and Brown 2011). When chilling requirements are not met, foliation is delayed and flowering is irregular and occurs over a longer period, resulting in varying fruit sizes and maturity stages at the time of harvest and even in poor pollination if synchrony of male and female flowering is required for pollination (Byrne and Bacon; Luedeling et al. 2009). Thus, possible warming raises concerns regarding crop quality and yield, if perennial trees do not fulfill their chilling requirements.

2.04.2.2 Springtime Freeze Risk

For many current areas of perennial crop production, damaging springtime temperatures is the single most important climate-related risk factor (Flore 1994). Springtime freezes can be classified as either an inversion (radiation) freeze or a wind (advection) freeze (Winkler et al. in press). Estimating the temperature at which damage occurs to flower buds is challenging, due to the confounding factors of growth stage and ambient conditions, and published temperature thresholds (e.g., Longstroth 2007) are likely a more appropriate reference for inversion freezes compared to wind freezes. Damages associated with wind freezes may occur at warmer temperatures than the published temperatures, especially if the period of cold temperatures is prolonged and/or the flower buds are wet due to precipitation (Longstroth 2007).

Considerable uncertainty exists regarding the future susceptibility of perennial crops to below freezing temperatures when preceding crop development is considered. Early spring warm-ups may result in greater freeze risk if flower buds are at a more advanced stage of development at the time of the last spring freeze. On the other hand, if the date of the last spring freeze advances to an earlier date in synchrony with bud development, spring freeze risk may not change or even decrease. Thus, a warmer climate cannot be assumed to bring more favorable conditions for perennial crops that currently are vulnerable to springtime freeze damage.

2.04.2.3 Pollination Constraints

Conditions favorable for pollination vary with species. For example, Lobell and Field (2011) argue that below average temperatures during the bloom season lead to a longer pollination period for almonds, as the stigma is receptive to pollen for longer periods of time. Consequently, warming during the bloom period could contribute to reduced yield. On the other hand, pollination of highbush blueberry in the Great Lakes region of North America is negatively impacted by cool, moist conditions (Tuell and Isaacs 2010). Bees are essential for pollination, and their activity is reduced under unfavorable weather conditions such as temperatures below 12 °C and wind speeds greater than 25 km h^{-1} (Thomson 1996). Warmer temperatures, if also accompanied by light winds and dry conditions, could result in greater pollination for this region and crop type.

2.04.2.4 Heat Stress

Heat and drought spells during the growing season are a concern for most perennial crops, as temperature and moisture availability directly influence photosynthesis, fruit size and quality, and harvest time. As summarized by Moretti et al. (2010), more heat can lead to higher sugar content (e.g., apples, grapes), lower levels of tartaric acid (e.g., grapes), lower fruit firmness (e.g., avocado), and higher antioxidant activity (e.g., strawberries). Higher temperatures can additionally reduce vitamin content of some fruit crops (McKeon et al. 2006). Physical damage is also possible including burning of walnuts (Baldocchi and Wong 2008) or sunburn and loss of texture in apples (Ferguson et al. 1999). When wine grapes are exposed to prolonged periods of high temperature, plant heat stress can lead to premature veraison (i.e., onset of ripening), the separation of berries from vines, enzyme inactivation, and failure of flavor ripening (White et al. 2006).

2.04.2.5 Disease and Insect Pest Damage

A confounding factor when considering climate impacts on perennial crop production is the frequency and severity of insect pests and plant diseases. Insect pests are poikilothermic; that is, their growth and development is primarily temperature dependent. Thus, the number of insect generations per year and their timing with respect to plant development stages are sensitive to a perturbed climate. For example, annual monitoring of codling moth (*Cydia pomonella*) in Germany's northernmost apple growing region (Lower Elbe valley) points to the occurrence of a partial second generation during warm years such as 2006, 2008, and 2010, and a climate impact analysis suggests possible future increases in the annual number of codling moth generations in all German fruit growing regions (Chmielewski et al. 2009). Also, increased insect pest populations could lead to early leaf abscission, which in turn contributes to an early loss of photosynthetic capability and therefore lower accumulation of total carbohydrates in perennial organs. For example, in sour cherry early defoliation delayed acclimation in the fall and induced a more rapid deacclimation in the spring, reducing bud survival and fruit set (Howell and Stackhouse 1973).

The severity of plant disease outbreaks is influenced by moisture conditions in addition to temperature. For example, Ladányi et al. (2010) found that rain during the bloom period promotes bacterial and fungal diseases in sour cherries. Further, *Diplodia seriata*, a cause of black rot of apples, is a new pathogen in the Lower Elbe valley whose appearance is probably associated with higher temperatures and more frequent rainstorm events during the the vegetation period (Weber 2009).

Future changes in plant development and insect and disease pressure might necessitate different approaches for the use of pesticides and disease protection management strategies

(Khanizadeh 2007). A number of current management strategies, such as chemical sprays, are restricted to certain growth stages or specified times before harvest, and changes in the timing of insect life cycles or disease occurrence with respect to crop growth stages could make these strategies no longer viable Winkler et al. (2002).

2.04.3 Nonclimatic Contributions to Vulnerability

Climate is not the only consideration when assessing the long-term viability of perennial crop production. Economic and social factors must also be considered. Specific concerns will vary with crop type and location, but most industry stakeholders must contend with changes in consumer demand, competing land uses, and competition with other production regions. The sour (tart) cherry industry in the United States is used here to illustrate these concerns.

While relatively small in scope, sour cherry production has major economic impacts at the local and regional levels. Production in the United States occurs primarily in the lake-modified zones surrounding the Great Lakes. In 2009, 292 million pounds of sour cherries, or 80% of the national total, were produced in Michigan, New York, Pennsylvania, and Wisconsin (NASS 2011). Of this amount, 266 million pounds were produced in Michigan alone.

Changes in consumer demand have been a particular concern for the sour cherry industry in the United States. The majority of product exchange is as processed products, with frozen sour cherries an intermediate product destined for use in the further processed ingredient and bakery industries (Thornsbury and Woods 2005). However, changes in American dietary patterns have reduced the demand for sour cherries by the bakery industry, forcing industry stakeholders to search for alternative uses of their product. The Cherry Marketing Institute, located in Michigan, has launched a ‘Go red instead’ campaign, advertising the high antioxidant content and health benefits of sour cherries (Cherry Marketing Institute), and the health foods industry is becoming an increasingly important commercial outlet for sour cherry production.

Competing land uses are also a concern. Orchards are typically located on hilltops and slopes near the Great Lakes shoreline in a scenic environment and sought after area for vacation homes. Many local planning organizations have recognized the contribution of the orchards to the allure of the local environment with some areas putting in place regulations to limit housing development, but, nonetheless, development pressure contributes to the vulnerability of the sour cherry industry in the Great Lakes region. Furthermore, sour cherry production is competing for orchard sites with wine grape production, which has increased substantially in size over the past several decades.

Competition with other production regions is also a growing concern. Historically, the United States imported very little in terms of sour cherry products, relying instead on a nationally produced product. However, after the near-complete crop failure in northwest Michigan in 2002 due to a springtime wind freeze, sour cherries were imported to the United States to sustain current markets, with most fruit imported from Poland – the current world leader in sour cherry exports and where the sour cherry industry has recently rapidly expanded (Thornsbury and Woods 2005). Although imports from Poland and other producing regions have since declined with improved production in Michigan and other cherry producing states, sour cherry imports remain at a higher level than before the 2002 crop failure (Thornsbury and Woods 2005). Importation remains elevated in part because Schatten Morello, the sour cherry variety grown in Poland and several other European production regions, differs from the cultivar Montmorency primarily grown in Michigan in terms of fruit color, taste, and other physical characteristics. Thus, the two cherry cultivars are not perfect substitutes for each other.

Additional nonclimatic factors that can contribute to the vulnerability of commercial sour cherry production and other perennial crops include uneven changes in wealth effects, influencing patterns of supply and mix of goods demanded, and political actions in response to environmental or trade concerns that lead to changes in subsidies (Winkler et al. 2010). These factors, along with changes in consumer demand, land use pressure, and competition with other production regions, may make investments in perennial crops unappealing to the individual producer.

2.04.4 Methods and Models for Assessing Climate Impacts on Perennial Crops

In contrast to assessments for annual crops, where the focus is often on potential changes in yield as estimated from well-known process-based models, climate assessments for perennial crops heavily rely on empirical relationships developed between climate observations and plant phenology, and, less frequently, between climate observations and yield. A number of empirical approaches have been applied, all of which have strengths and weaknesses that must be considered when interpreting the outcomes of assessment studies. Below we highlight several analysis and modeling approaches that have been frequently utilized for assessments of climate impacts on perennial crops. These methods, along with climate inputs and typical outcomes, are summarized in Figure 2.

2.04.4.1 Critical Thresholds, Growing Degree Days, and Agro-Climatic Indices

Critical thresholds represent perhaps the simplest approach for evaluating climate impacts, and many applications appear in the literature (e.g., Winkler et al. 2002; Zavalloni et al. 2006a,b; Rochette et al. 2004). As a more recent example, Ladányi et al. (2010) argued that the 10 days before and during bloom had the greatest impact on sour cherry quality and yield in Hungary and explored the effect of changes in the frequency of several critical thresholds. These thresholds were selected to assess freeze risk and conditions for pollination, and included the number of days with minimum temperatures below 0 °C and precipitation greater than 5 mm. The advantage of critical thresholds is their modest data requirements and computational costs, whereas a disadvantage is the difficulty in identifying appropriate threshold values. Critical thresholds can vary with variety and cultivar, and field trials and growth chamber

experiments are often unavailable for the crop variety or cultivar of interest.

Growing degree days (GDD), typically calculated as the difference between the daily mean temperature and a specified base temperature, have also been widely used in assessment studies for perennial crops, particularly to estimate the timing of different phenological stages (e.g., Nemani et al. 2001; Winkler et al. 2002; Zavalloni et al. 2006a,b) (Figure 3). For example, the Baskerville-Emin method (1969) was used to calculate growing degree days (base value 5 °C) beginning from 1 January for the sour cherry production regions of Michigan (USA), and early bud development (e.g., 'side green') was estimated to occur when ~150 growing degree days was reached (Winkler et al. in press). The degree day concept can also be used to evaluate changes in cold intensity and duration, as shown by Rochette et al. (2004). In this case, 'cold' degree days were defined as the degree days below a base value of $-15\,^{\circ}\mathrm{C}$ and were accumulated for the period 1 August–31 July. Additionally, some authors have employed modified degree day calculations, such as the Huglin Index (Duchêne and Schneider 2005) which weights daily maximum temperature more than minimum temperature in order to better represent species-specific development requirements, or biologically effective degree days (BEDD) that restrict the maximum heat accumulation for a particular day to emulate the reduction in growth rate at high temperatures (Hall and Jones 2008). Blümel and Chmielewski (2012) found that incorporating a day length term into a GDD model markedly improved projections of the timing of fruit tree blossom. Often times critical thresholds and heat accumulation are considered jointly; for example, growing degree day accumulation at the time of the last spring freeze (e.g., the last occurrence in spring of minimum temperature ≤ 0 °C) can provide an indication of temporal changes in crop susceptibility to damaging cold temperatures (Winkler et al. 2012, in press).

Growing degree days
Bloom
Pollination
Bud loss due to cold injury

Figure 3 Growing degree days (also referred to as forcing units) are frequently used to estimate growth stages of perennial crops. In this example for sour cherry production, growing degree days are used to estimate the (1) timing of side green (a critical growth stage that occurs soon after bud swell), (2) the timing of flower bloom, (3) crop development at the time of last spring freeze and consequent bud loss, and (4) the timing of pollination. This image was prepared by Andresen, J. A., J. R. Black, C. Zavalloni, J. M. Bisanz, and H. K. Min at Michigan State University for the Pileus Project website (http://www.pileus.msu.edu/) and used here with their permission.

Agro-climatic indices are simply the expression of one or more climate variables in terms reflective of conditions important to crop development. These indices are often used to judge the suitability of a particular region for crop production, and have been a particularly popular approach for assessing suitable areas for quality wine production (e.g., Jones and Davis 2000; Hall and Jones 2008). As an example, White et al.

(2006) developed a nominal, four-category index for identifying premium wine grape producing areas in the United States based on the frequency of hot and cold days, diurnal temperature range in the growing and ripening seasons, and average temperature and heat accumulation during the growing season.

2.04.4.2 Modeling the Break of Dormancy

Models used to estimate whether perennial crops have met their chilling requirement for break of winter dormancy are collectively referred to as 'chill models.' Several chill models currently exist, although all are based on the concepts of growing degree days and critical thresholds. A commonly used but relatively simple model is the Chilling Hours Model, also referred to as the Weinberger Model (Weinberger 1950). This model requires hourly temperature measurements as input, and chilling is simply calculated as the sum of hours when the temperature falls between the thresholds of 0 and 7.2 °C. The user needs to fix the time period for the summation, which can vary by location and variety, although a frequent summation period (for Northern Hemisphere locations) is 1 November–1 March (Luedeling et al. 2009). In contrast, the popular Utah Model (Richardson et al. 1974) assigns different chilling efficiencies to different temperature ranges (Luedeling and Brown 2011), and includes the concept of negative chilling accumulation or chilling negation with temperatures above 15.9 °C assigned negative chill units (Byrne and Bacon). The Dynamic Model (Erez et al. 1990) represents a more complex formulation. The underlying assumption is that dormancy completion depends on the level of a dormancy-breaking factor that accumulates in flower buds (Erez et al. 1990). As summarized by Luedeling et al. (2009), initially an intermediate accumulation product is formed in a process promoted by cold temperatures, with warm temperatures able to destroy this product. Low temperature efficiency in releasing buds from rest follows an optimum curve where the maximum efficiency is between 6 and 10 °C (Erez and Lavee 1971). Higher temperatures produce negative effects and result in negation of a certain amount of hours of chilling units depending on the species and cultivar (Erez et al. 1979). Once a critical level of the intermediate product is amassed, it is irreversibly transformed into a Chill Portion, which can no longer be destroyed (Luedeling and Brown 2011.) An advantage of the Utah Model and the Dynamic Model over the older Chilling Hours Model is that end and start dates for chilling accumulation do not need to be prescribed, as both models can account for the reversibility of the chilling process when temperatures are high (Luedeling et al. 2009).

A major concern of all chill models is their applicability outside the region for which they were initially developed, especially as the models are often extrapolated to other locations with little or no change in the original parameters and critical temperatures. Luedeling and Brown (2011, p. 411) recently expressed their concern that users "assume that the choice of chill model is not important and that estimates of species chilling requirements are valid across growing regions." This concern is particularly critical for climate assessments, as biases resulting from the misapplication of chill models may provide a misleading interpretation of plausible future changes in the spatial distribution of production regions. Recent comparisons of the output of the chill models at multiple locations worldwide provide credence to this concern and suggest that site-specific correction factors are likely needed in order to facilitate spatial comparisons (Luedeling and Brown 2011).

Another constraint when applying chill models is the need for hourly temperature data. Hourly observations are available for a much smaller subset of climate observing stations compared to daily temperature observations. Consequently, subregional variations in chill units often cannot be captured by the coarse spatial resolution of hourly observing networks, particularly in areas of complex topography where temperature is highly associated with landscape position (i.e., aspect, elevation).

2.04.4.3 Estimating the Timing of Growth Stages

Phenological modeling is an important component of many climate assessments for perennial crops. Some phenological models are purely statistical in character such as the model developed by Zavalloni et al. (2006a) that relates flower bud phenological stages for sour cherries to growing degree accumulations. Others are somewhat more mechanistic in concept and attempt to simulate the processes of chilling and subsequent heat accumulation (e.g., Chuine et al. 1998). Recently, Chmielewski et al. (2011) evaluated the ability of five representative phenological models to estimate apple blossom in Germany. The comparison included a phenological model that assumes chilling is completed by 1 January and estimates blossom time based on a temperature forcing rate function, a slightly more complex model that assumes forcing temperatures are not effective until chilling is met and estimates both chilling rates and a forcing rate function, two 'parallel' models that assume chilling and forcing can occur simultaneously but differ in terms of how the chilling and forcing rates are calculated, and a simple statistical model employing mean temperatures for the period February–April as predictors of apple blossom. All five models were found to satisfactorily simulate the beginning of apple blossom for a wide range of apple cultivars, although the error was smallest for the combined chilling–forcing models. Furthermore, all five models performed well even though daily, rather than hourly, temperature series were used as model input. These findings suggest that at least some phenological models can be employed to estimate the beginning of blossom for multiple cultivars and geographic regions, although further evaluation for a larger number of crops and locations is needed. Recently developed phenological models that incorporate day length, in addition to chilling and heat accumulation (Blümel and Chmielewski 2012), appear to perform well in different geographic regions and have utility for climate assessments (Matzneller et al. 2012, manuscript submitted to *Agric. Forest Meteorol.*).

2.04.4.4 Empirical Yield Models for Perennial Crops

As previously noted, few process-based yield models exist for perennial crops. One exception is the CropSyst modeling system, a relatively simple generic (i.e., multi-crop) daily time step simulation model that includes an orchard–vineyard module (Stöckle et al. 2010). As noted by the developers, the extension of CropSyst to perennial crops is still in its early stages, and its performance across a wide range of perennial crops and locations remains largely untested. Empirical methods continue to be the primary approach for estimating yield for perennial crops, although the resulting models are specific to an individual location and crop type (or even cultivar). The development of empirical yield models has proven to be a demanding, often frustrating, undertaking. Two recent papers, describing the development of state-level (Lobell et al. 2006) and county-level (Lobell and Field 2011) empirical yield models for perennial crops in California, highlight the many challenges in empirical yield model construction. Yield models were developed at two very different spatial scales, since, as pointed out by Lobell and Field (2011), the spatial scale (e.g., station, county, state) for model development is not intuitive, and is often dictated by the availability and spatial coverage of weather, production, and yield measurements rather than by theoretical and statistical considerations. An advantage of the county-level models is the greater range of values for the predictor variables (monthly temperature and precipitation for the California models), whereas an advantage of the state-level models is that they are not as susceptible to omitted variable bias compared to the county-level models, where variations between counties may be a function of other factors (e.g., soil) besides climate (Lobell and Field 2011). Another challenge is that the explained variance of the empirical yield models is often very modest. In fact, Lobell and Field (2011) found that the county-level empirical relationships were significant for only 8 (almonds, wine grapes, strawberries, hay, walnuts, table grapes, freestone peaches, and cherries) out of the 20 perennial crops for which models were developed. Even for these eight crops, the explained variance when the models were applied to a test period hovered only around 20%. One reason for the low explained variance is that mean values of temperature and precipitation, which are commonly used predictors, are not sufficiently capturing the physical processes contributing to yield variations. Furthermore, the spatial aggregation masks considerable spatial variability in climate conditions and in the quality of orchard and vineyard sites. The choice of spatial aggregation level can also result in different interpretations of the impacts of climate on yield. Lobell and Field (2011) found, for instance, that the county-level model for almonds suggested a small beneficial effect of warming temperatures on yield, whereas the state-level model suggested a negative effect. These differences led Lobell and Field (2011) to argue for greater effort to verify the signs of model coefficients, including surveying growers to obtain their input on the importance (and direction) of weather variables on yield.

Empirical yield models have numerous additional constraints – management practices are usually considered constant, temporal trends in yield due to improved technology need to be removed, CO_2 fertilization is rarely included, linking statistical relationships to physical processes is difficult, and, like all empirical models, the validity of the yield models is questionable outside the range of the data used in the model development (Lobell and Field 2011). This latter issue is of particular concern for climate studies, as the range of values of the predictor variables, particularly maximum and minimum temperature, could shift in the future.

2.04.4.5 Field and Greenhouse Experiments

In addition to the empirical and modeling approaches described above, a limited number of field and/or greenhouse experiments have been conducted for perennial crops, particularly to investigate the impacts of changes in carbon dioxide (CO_2) concentrations on crop growth and development. For example, Idso et al. (1991) exposed sour orange trees to elevated CO_2 concentrations to investigate changes in photosynthesis rate, whereas Allen and Vu (2009) considered the impact of CO_2 enrichment on leaf and root development for sweet orange trees.

2.04.5 Perennial Crop Production and Historical Climate Variability

Synthesis of the numerous studies that have investigated the impacts of historical climate on perennial crops is challenging as differences are expected by geographic region and crop type. Most analyses of the influence of historical climate variability focused on the timing of phenological stages, and, in general, these studies found that crop growth has advanced earlier in the year. For example, an increase of 0.06 °C per annum in average springtime temperatures appears to be associated with an earlier and shorter period between budburst, flowering, and harvest of wine grapes in France (Duchéne and Schneider 2005). Similar results were found by Jones and Davis (2000), who observed a shortening of growth intervals and lengthening of growing season for wine grapes.

Additionally, warming trends in Japan appear to have contributed to an advancement in phenology for apple and cherry trees (Fujisawa and Kobayashi 2010; Primack et al. 2009) and to earlier flowering dates for apricots (Doi 2007). Similarly, earlier flowering times for apples and pears in France have been observed (Atauri et al. 2010). Noticeable advances in leaf unfolding, flowering, and fruiting have been observed in recent decades for fruit trees in the western Mediterranean, which have been accompanied by an increase of over 2 weeks in the length of the growing season and less spatial variability in the timing of phenological stages (Gordo and Sanz 2009). Advanced timing of springtime phenophases for apple and sweet cherry trees in Germany is correlated with an earlier beginning of the growing season (Chmielewski et al. 2004), while cherry trees in Switzerland have displayed an earlier appearance of springtime phenological phases, and although less pronounced, later phases in autumn (Defila and Clot 2001). Warming trends were also associated with observed advances in spring phenology ranging from 2 to 8 days for the period 1965–2001 for apples and grapes in the Northeastern United States (Wolfe et al. 2005). As a consequence of warming, suitable climate conditions for apple production have moved inland and northward in Finland, as the risk of extreme low temperatures decreased from ~1980 to 2000 (Kaukoranta et al. 2010). Several studies indicate that damage accruing from spring frost is decreasing. For example, there has been a general reduction in the risk of spring frost in recent decades for apples in Trentino, Italy (Eccel et al. 2009). In the western United States, both late spring and early fall freeze events are becoming less common, and the area is now more conducive to the ripening of wine grapes (Jones 2005).

Negative consequences of observed warming have also been reported. All major wine grape growing regions across the world have experienced warming during the growing season, but 12 out of the 27 regions experienced a decline in production associated with optimum growing season temperatures above vintage ratings (Jones et al. 2005). Ramos et al. (2008) reported that a warming of 1.0–2.2 °C during the growing season led to an increase in heat accumulation for wine grapes in Spain and resulted in a 6–14% increase in water demand.

Winter damage is another factor that may affect the productivity of perennial trees. Studies of grapes, peach, apricot, sweet cherry, pear, and apples in the Okanagan Valley of British Columbia reveal that poor fruit production was due to winter freeze events caused by more frequent Arctic airflow in November–December than in the past (Quamme et al. 2010; Caprio and Quamme 1999, 2006). Modeling experiments conducted by Marshall et al. (2003, 2004) suggest that land use change might have exacerbated freeze risk in the citrus production regions of south Florida, as minimum temperatures were warmer, and below freezing temperatures persisted for a shorter period, for the model simulations that employed pre-1900s land cover compared to those with near present day land cover.

Analyses of the impact of historical climate trends on the break of dormancy for grapes, kiwi, peach, and sweet cherry in California indicate that most locations experienced a significant negative trend in winter chill hours (Baldocchi and Wong 2006). In a later study, trends in winter chill in the Central Valley of California for fruits and nuts were observed to range between −50 and −260 chilling hours per decade (Baldocchi and Wong 2008). Hennessy and Clayton-Greene (1995) analyzed a number of high-chill fruits in Australia (e.g., plum, apple, pear, cherry, peach, and apricot) and demonstrated that warming causes greater reduction in chilling at sites with a higher mean temperature and a wider diurnal temperature range.

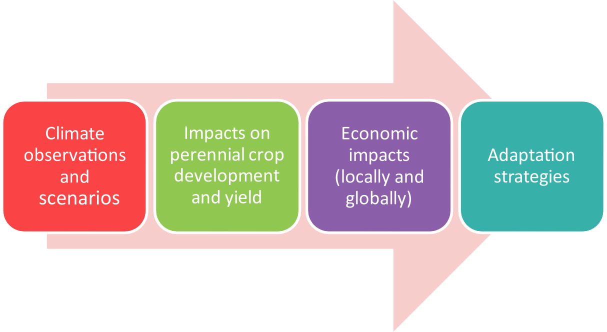
Although not as widely studied, precipitation variability also plays a role in the productivity of perennial fruit trees. For example, a slight decrease in precipitation during the bloom to veraison period resulted in plant water stress in a study involving wine grapes in Spain (Ramos et al. 2008). In contrast, Zavalloni et al. (2008) found that the amount of precipitation preceding the end of the previous growing season helped to explain historical yield variations of sour cherries in Michigan (USA).

2.04.6 CO_2 Fertilization

A modest number of studies have investigated the potential impacts of CO_2 enrichment on crop growth and development. In a relatively early study, photosynthesis rates were found to increase when sour orange trees were exposed to elevated CO_2 concentrations (Idso et al. 1991). More recently, Allen and Vu (2009) found that young sweet orange trees grown in greenhouses displayed increased photosynthetic rates, but decreased leaf development and fine root biomass, with elevated CO_2 concentrations. A 2-year FACE (Free Air CO_2 Enrichment) experiment for wine grapes suggested that elevated CO_2 concentrations have an early season effect on fruit dry weight and concentrations of tartaric acid and total sugar, but by the time the grapes reach maturity there was little evidence of any impact of CO_2 fertilization on grape quality (Bindi et al. 2001). In terms of yield, a 3-year open top chamber study found grape yields increased under elevated CO_2 concentrations in the Mediterranean (Moutinho-Pereira et al. 2009). These short-term experiments suggest a complex relationship between CO_2 fertilization and perennial crop growth and development, although the impacts of CO_2 fertilization over the entire lifetime of an orchard are still largely unknown. Furthermore, differences in the impacts of CO_2 fertilization by species and cultivar are not well documented.

2.04.7 Potential Impacts of Climate Change on Perennial Crops

In addition to CO_2 fertilization, future changes in temperature, precipitation, humidity, wind, thunderstorm and hail frequency, and other climate variables could have a substantial impact on perennial crop production. The majority of studies that have investigated potential future impacts for perennial crops have applied a 'feed-forward' assessment strategy, as illustrated in Figure 4. Commonly, climate scenarios (also referred to as climate projections) were substituted in place of observations as input to chill, phenology, and yield models or to calculate heat accumulation, agro-climatic indices, water budgets, or pest and disease frequency. A climate scenario is simply an internally, consistent, and plausible future state (Carter et al. 1996). A climate scenario should be carefully distinguished from a 'prediction' or 'forecast,' as it involves numerous assumptions that may or may not be realized (Mearns et al. 2001). Furthermore, climate scenarios only provide a subset of possible future climate conditions (Jones 2000). For the most part, the climate scenarios that have been used for climate assessments of perennial crops were obtained by 'downscaling' coarse-scale output from global climate models to the local or regional scale. In the discussion below,



Climate observations and scenarios
Impacts on perennial crop development and yield
Economic impacts (locally and globally)
Adaptation strategies

Figure 4 An idealized feed-forward approach to the investigation of plausible impacts of climate on perennial crops. The vast majority of previous impact assessments have included only the first two steps shown in the figure. Potential economic impacts and adaptation strategies are infrequently addressed and represent a substantial gap in the understanding of climate impacts on perennial crops.

we focus on potential future impacts on perennial crop development and yield. Ideally, a feed-forward approach also includes an evaluation of potential economic impacts and adaptation strategies (the third and fourth steps shown in **Figure 4**), although only a few previous studies of climate change impacts on perennial crops have included an economic component and little research has been conducted on future adaptation options.

Some perennial crops, including apples, could cope better with cold winter temperatures if warmer temperatures linger later into the autumn (Rochette et al. 2004) and the frequency of extreme cold events decreases (Baraer et al. 2010). Consequently, since bud hardening is in part a function of a photoperiod, cold temperatures might not occur until after trees and vines are sufficiently protected by fall hardening (Rochette et al. 2004; Jones 2005). However, despite such an increase in cold hardiness, the risk of winterkill could increase, as suggested by impact analyses for various tree fruits and grapes in eastern Canada (Rochette et al. 2004) and apple production in Finland (Kaukoranta et al. 2010). If there are greater fluctuations in winter temperatures, warm spells might cause a break in dormancy and leave trees at a higher risk of damage by subsequent extreme cold temperatures.

Chilling hours would be reduced with warmer winters, and chilling requirements might not be met as quickly as they have been in the past. Fulfillment of chilling hour requirements has been identified as a potential problem for grape production in Australia (Webb et al. 2007), apple production in Britain (Cannell and Smith 1986), and the production of various fruits in southern Australia (Hennessy and Clayton-Greene 1995) and the Central Valley of California (Baldocchi and Wong 2008). However, one of the greatest concerns for perennial crops is the possibility for warmer temperatures in late winter and early spring. Bud break is strongly related to heat accumulation, and with warmer temperatures in late winter and early spring many fruit and nut trees might reach bud break earlier than they do at present (Cannell and Smith 1986; Rochette et al. 2004; Webb et al. 2007; Kaukoranta et al. 2010; Blümel and Chmielewski 2011). With earlier bud break and flowering, tree fruit may have an increased risk of frost damage as is suggested by analyses of apple production in Finland (Kaukoranta et al. 2010), and apple, pear, peach, apricot, sweet cherry, plum, and grape production in eastern Canada (Rochette et al. 2004). Others have suggested that plants may physiologically acclimate to a warmer climate and thus reduce the plant's risk of frost damage (Eccel et al. 2009).

Higher temperatures during the warmest part of the growing season also might have substantial impacts on perennial crop production. Impact studies investigating grape and wine production in the western United States (Jones 2005), Italy (Bindi et al. 1996), and across the globe (Jones et al. 2005) suggest that temperatures could become too warm for optimal fruit growth or that wine quality may be affected. Warmer temperatures have also been found to speed the phenology of perennial crops, sometimes resulting in earlier harvest dates (Webb et al. 2007).

Regional variations in potential climate impacts also occur and will continue. For example, warmer temperatures could, depending on location and current conditions, negatively or positively impact wine quality (Jones et al. 2005). In more northerly production areas, citrus crops might benefit from warmer temperatures in winter because the risk of frost decreases, but more southerly production areas may see a decrease in productivity due to temperatures that are warmer than optimal (Rosenzweig et al. 1996; Tubiello et al. 2002). Additionally, if the spatial patterns of temperature and precipitation change, it is possible that the distribution of the varieties that are grown would shift; several authors have already indicated that this is a distinct possibility for wine grape production in some regions (Kenny and Harrison 1992; Hall and Jones 2008).

A limited number of studies have investigated the sensitivity of future changes in yield to climatic conditions. Increased temperatures might increase wine production in Portugal, although decreases in rainfall may limit production in some regions (Gouveia et al. 2011; Santos et al. 2011). Some locations may be relatively insensitive to changes in local and regional climatic conditions with only very small changes in yield, as is suggested by an analysis of the productivity of grapes, oranges, and avocados in California (Lobell et al. 2006). Similarly, an assessment conducted by Stöckle et al. (2010) suggests that apple production in eastern Washington might only decrease slightly with perturbed climatic conditions.

Warmer temperatures might also have indirect impacts on perennial crop production in the form of diseases and pests. With longer and warmer growing seasons, it is possible that the number of insect generations during a given season would increase and that the timing of insect infestations might differ significantly from what they are presently, as suggested for apple codling moth in the Great Lakes region of North American (Winkler et al. 2002). An increase in wet weather during the blooming period might reduce the effectiveness of pollination in plants and also cause increased problems with bacterial and fungal diseases (Ladányi et al. 2010).

2.04.8 Adaptation Options

Climate significantly influences perennial crop development, quality, and yield, and this clearly points to the need to consider options for adapting to a spectrum of future climate conditions. Numerous options have been proposed for adapting to climate-related risk. For example, low chill cultivars and dormancy-breaking chemicals are two possible adaptation options for areas where chilling requirements may not be met in the future (Luedeling et al. 2009). Cold-resistant cultivars and frost protection (e.g., sprinklers) are potential adaptation strategies where springtime freeze hazard may increase, and breeding for heat resistance cultivars is one strategy for locations where warmer temperatures might occur during the growing season. Irrigation may be a feasible adaptation strategy for some areas where water stress increases, and hail nets are options if thunderstorms frequency increase (**Figure 5**). More generically, management practices that influence an orchard's microclimate (e.g., planting density and pruning; Luedeling et al. 2009) can help adapt to a number of climate-related risks. A more extreme adaptation option is a switch in land use, either to another crop type or to a nonagricultural use. Although most of the studies that we reviewed acknowledged

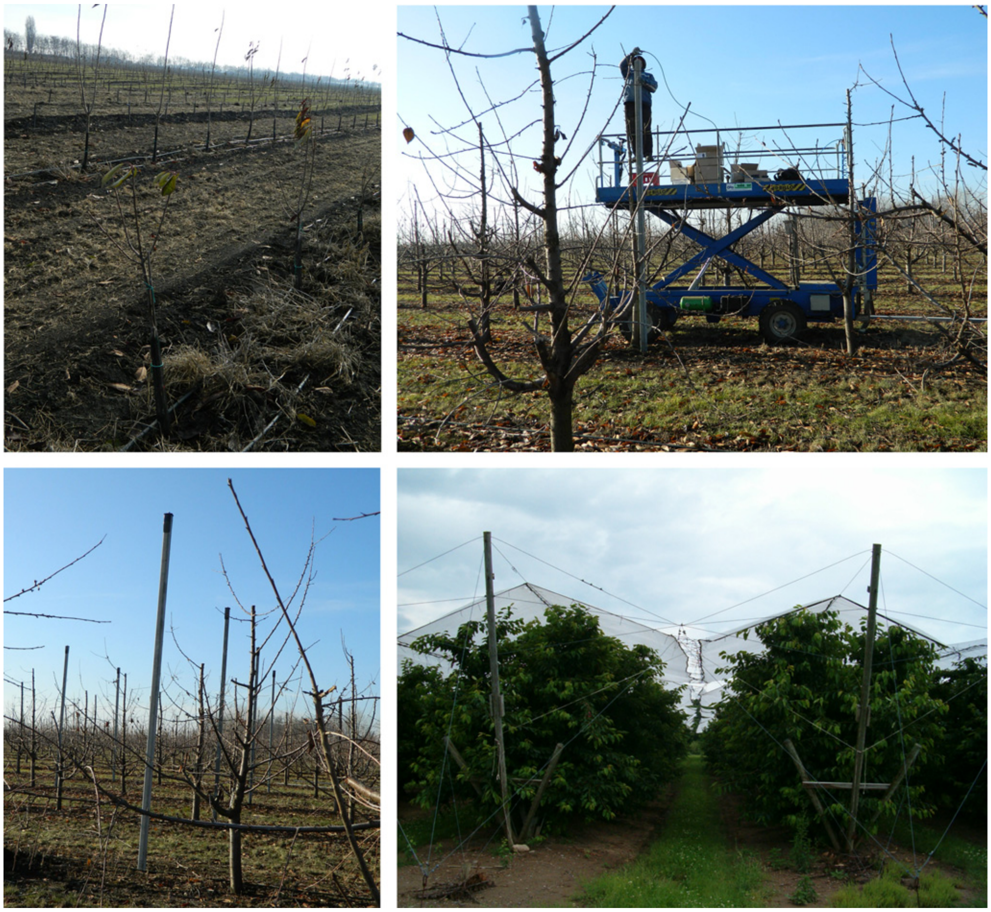


Figure 5 Example adaptation options for perennial crops. Upper left: An irrigated sour cherry orchard in Hungary. Upper right: Workers installing supports for hail nets in a sour cherry orchard in Hungary. Lower left: Hungarian orchard with both irrigation and supports for hail nets. Lower right: Deployed hail nets in a sweet cherry orchard at Cornell University (USA). Photo credit: Dr. Geza Bujdosó, Research Institute for Fruit Growing and Ornamentals, Budapest, Hungary.

that adaptation options need to be considered, none systematically evaluated the feasibility and economic consequences of alternative adaptation options. In other words, previous research on future perennial crop production has stopped well short of a formal adaptation assessment.

2.04.9 Next Steps

The majority of the research discussed above focused on a location or a region. Recently, Winkler et al. (2010) highlighted the need for assessment strategies for international market systems that go beyond the local–regional focus of traditional climate assessments but that incorporate more detail than the broad, but often overly simplistic, approach of many cross-sectoral integrated assessments (e.g., Nordhaus 1994). Using the international sour cherry industry as an example, Winkler et al. (2010) called for an 'expanded impact assessment' that treats perennial crop systems as an international rather than local industry and that considers variations in climate-related risk between production regions. They further argued that temporal dynamics need to be included in the assessment process including changes in patterns of international trade, consumption, and production along with evolving adaptation strategies by industry stakeholder groups. To do this requires advances in crop modeling, preferably the development of process models that can be applied to multiple species and cultivars, improved availability and international exchange of climate and phenological observations for model development, the modification of currently available trade models for use in climate applications, improved models of individual decision making, and methods for evaluating adaptation options. Additionally, strategies need to be improved for communicating the 'meta-uncertainty' (Winkler et al. 2010) of the assessment outcomes to industry stakeholders. All these present considerable challenges but challenges that are more likely to be addressed with greater involvement of industry stakeholders throughout the assessment process.

2.04.10 Summary

Climate-related risk is large for perennial crops given their exposure to fluctuating weather conditions throughout the year. Key vulnerabilities include the fulfillment of winter chill requirements, springtime freeze risk, climate-related constraints on pollination, heat stress, and disease and insect pest pressure. A myriad of methods have been employed to evaluate the past and future climate vulnerability of perennial crops. Temporal and spatial changes in the frequency and timing of critical thresholds and heat accumulation have been particularly popular approaches to assessing past trends and potential future risk. Agro-climatic indices have been widely applied to evaluate the spatial distribution of suitable production regions. Modeling efforts remain largely empirical, although quasimechanistic phenological models exist in addition to empirical models. Impact assessments for perennial crops are handicapped by the lack of process-based crop development and yield models.

Analyses of the influence of historical climate variability on perennial crops, while varying by crop type and location, suggest earlier dates of bloom and other phenological stages and, for some locations, a reduction in spring and early fall freeze risk. Fruit quality appears to have suffered in some growing regions, and winter injury has increased in high latitude growing regions. Additionally, a negative trend in chilling hours has been observed for a number of species and production regions. Plausible future impacts under a warmer climate include fewer chilling hours, earlier bud break and bloom, changes in fruit quality as temperatures surpass crop-specific optimal temperatures, and reduced frequency of winter, but not necessarily springtime, cold temperature damage. Several analyses suggest that pest and disease risk could increase in the future, with an increase in the number of insect generations per season and the frequency of bacterial and fungal diseases.

Climate assessments for perennial crops need to move beyond the local and regional scales, and recognize that perennial crops constitute an international market system with multiple production regions with varying climate-related risk and that market systems respond to changes in demand, as well as changes in supply. Additionally, grower decision making and adaptation options need to be more formally addressed. Climate assessments for perennial crops will benefit from greater stakeholder input.

Acknowledgments

The development of this chapter was partially supported by NSF Award CNH 0909378. The manuscript originated as a class project for Geography 892 (Seminar on Climate Science) at Michigan State University. The authors thank Frank-M. Chmielewski (Faculty of Agriculture and Horticulture, Humboldt University) and Robert Kurlus (Department of Pomology, Poznan University of Life Sciences) for their helpful comments on an earlier version of the manuscript. Our thanks also to Geza Bujdosó (Research Institute for Fruit Growing and Ornamentals) for providing the photographs of irrigation and hail nets in sour cherry orchards. Finally, the authors express their thanks to their colleagues of the previous Pileus Project and current CLIMARK Project. The chapter content was greatly informed by insights gained from these efforts, including from interactions with industry stakeholders.

Glossary

Association mapping Method for detecting genetic loci that influence phenotypic traits based on linkage relationships in collections of genetic materials.

Bacillus subtilis Common bacteria found in the soil, air, water, and decomposing plant tissue. Laboratory strains are used for transformation of genes into plant tissue.

Chaperone (Molecular) A group of diverse proteins supervising in the correct folding, assembly of polypeptides, protein formation, and protein complexes.

Cytokinin Plant hormone synthesized by the roots, where it is translocated upward into the plant shoots. It is involved in promoting cell division, tissue growth, and budding.

Ethylene Gaseous, organic hormone produced by plants involved in fruit ripening, seed germination, senescence, and other elements of plant development.

Genomic selection A form of genetic selection that uses DNA markers covering the genome to detect and select for quantitative trait loci (QTL) influencing key traits.

Stacking The integration of multiple genetic traits into a single genetic background.

2.05.1 Plant Breeding: A Science for Change

The Neolithic Revolution marks the extended transition of human lifestyles from hunting and gathering to agriculture. As the cultivation of plants became more prevalent, primitive societies around the world began selecting plant types from their respective geographical regions and planting the seeds of the most productive or attractive types in the next season (Fuller et al. 2011). This selection pressure resulted in a shift in plant types, a "domestication syndrome" that favored plants that were easily harvested and stored for processing and consumption at a later date (Allard 1999).

Although plant selection by farmers and hobbyists occurred over thousands of years, it is only recently that plant breeding was recognized as a science. The science of plant breeding involves making deliberate crosses between individuals with complementary attributes and applying genetic principles to the progeny to develop new cultivars with desired characteristics. Perhaps the best known example demonstrating the power of plant breeding for engineering new plant types with yield enhancing characteristics is highlighted by the successes of Dr Norman Borlaug. Dr Borlaug began his innovative research at the International Maize and Wheat Improvement Center (CIMMYT) in Mexico to develop wheat varieties with multiple "famine resistance" traits, including semidwarfism, yield stability, broad adaptability, and tolerance to abiotic and biotic stresses. Dr Borlaug's vision for crop improvement led to the development of new wheat cultivars that played a key role in achieving food security for many developing countries in the 1960s and 1970s, sparking what is now called the Green Revolution (Khush 2001). Plant breeding successes in wheat were translated to rice and resulted in even more widespread impacts of crop improvement on global food security. Although years of continuous research were required to accumulate various crop adaptation traits into elite cultivars, the ultimate success of this effort resulted in Dr Borlaug's recognition with the Nobel Peace Prize in 1970 to commemorate his contributions to world peace through increasing and stabilizing the global food supply.

Plant breeding strategies to engineer plants for greater yield potential are well established. Global crop production has risen steadily since the Green Revolution (Figure 1). However, these advances in crop productivity may not be sufficient to meet future needs given a projected 39% increase in global population by 2050 (Population Reference Bureau). The trend is also flattening and large uncertainty exists regarding different stresses that can reduce the yield further in the future. This problem is exacerbated even further by the emerging threats listed in previous chapters. These challenges call for another Green Revolution to engineer new climate resilient crops.

2.05.2 Climatic Impacts on Crops

Agriculture and our global capacity for food production are highly vulnerable to the weather and climate patterns, especially the effects of rising or variable temperatures and drought. Plant yields are also expected to be vulnerable to inundation and flooding of coastal farmlands, as well as increase in soil salinity in various locations (Rignot et al. 2003; Saleemul et al. 2004). Climate variability and elevated daytime and nighttime temperatures and diurnal temperature ranges may even threaten soil nutrients such as nitrogen availability in some parts of the world through increased losses of nitrogen under elevated soil temperatures (Houghton et al. 2001; Parry et al. 2007; Smith et al. 2007).

Biotic stresses, including plant pathogens and insects, and their interaction with abiotic stresses present further challenges to global food production and security. Although not discussed in this perspective paper, the effects and interactions of biotic stresses and climate have been thoroughly reviewed by Atkinson and Urwin (2012), Luck et al. (2011), and Newton et al. (2011).

2.05.3 Advancements in Engineering Plants for Tolerance to Abiotic Stresses

Plant breeders are confronted with the task of creating new crop cultivars that can tolerate a wide range of environmental stresses. In the subsequent sections, we report on technological advancements in genetic technologies being developed to enhance crop performance under abiotic stresses including drought, heat, salinity, and flooding. A listing of new traits and technologies are summarized in Table 1.

2.05.3.1 Increased Tolerance to Drought

The agricultural enterprise is aware that the occurrence and severity of drought conditions will likely increase as temperatures rise. Drought is defined by the World Meteorological Organization as "a deficit of rainfall in respect to the long term mean" affecting a large area for one or several seasons or years (Hounam et al. 1975). Farmers and plant breeders are exploring opportunities to address this challenge using natural genetic variation as well as transgenic breeding methods and biotechnology.

Maize breeders commercially have been working for a number of years to increase the intrinsic levels of drought tolerance in hybrid maize. The strategy is to use forms of genomic selection and association mapping to identify native genes of maize that contribute to improved hybrid performance under drought. For example, researchers at Pioneer Hi-Bred are using an Advanced Yield Technology system to identify and stack multiple drought tolerance-related genes into elite hybrids. New hybrid cultivars are being commercialized under the brandname Optimum®AQUAmax™. Recent experiments conducted in Nebraska, California, Texas, Colorado, Kansas, and Oklahoma showed that AQUAmax™ hybrids exhibited 5% higher yields under water-limited situations compared with other commercial checks. This technology was commercially released in 2011 and targets dry land corn production systems in the Western Corn Belt of the United States (Dupont 2012; Pioneer 2012). Syngenta is using a similar gene stacking system called Gene Blueprinting Technology. Using this selection strategy, Syngenta has incorporated 12 genes involved in multiple drought tolerance pathways into elite hybrid backgrounds. Syngenta estimates that these hybrids have a 15% yield advantage in drought environments. These hybrids are being marketed under the brand name Agrisure Artesian™ Technology. This technology was commercialized in 2011 and is targeted for production environments in the Western Corn Belt of the United States (McCabe 2010; Syngenta Inc 2012).

Genetic engineering to enhance drought tolerance using transgenes is also being investigated. Monsanto Company in collaboration with BASF identified a cold shock protein B (*CspB*) from a soil bacterium *Bacillus subtilis* that provides enhanced hybrid performance under drought conditions. *CspB* is expressed under drought stress and acts as a RNA chaperone that aids in the unfolding of misfolded secondary RNA structures, thus allowing and facilitating RNA translation (Health Canada 2012; Reeves et al. 2009; Graumann and Marahiel

Table 1 Examples of technologies for engineering crop plants for abiotic stress tolerance

Abiotic stress	*Crop*	*Developing organization*	*Breeding method*	*Technology*	*Growing region*

1998). Monsanto is planning a limited release of *CspB* lines under the brand name First-Generation Drought-Tolerant Corn in the near future. Another technology called Second-Generation Drought-Tolerant Corn is in Phase 2 development within the Monsanto Pipeline and is designed to further enhance the performance of corn under drought stress (Monsanto Company 2012a). *CspB* technology is not limited to use in the United States. The Water Efficient Maize for Africa (WEMA) program is combining plant breeding for drought tolerance with the *CspB* transgene. Hybrid maize varieties that combine these technologies currently are being tested in drought-prone locations across Africa (Open Forum on Agricultural Biotechnology in Africa 2012). Although still very new, these genetic engineering approaches by Monsanto and other companies represent promising new strategies for engineering crop plants for tolerance to drought conditions.

2.05.3.2 Tolerance to Flooding and Submergence

With the increased potential for heavier rainfall and hydrological extremes, agricultural areas are susceptible to flooding and ponding. Plant breeders are identifying and developing genetic technologies to enhance crop productivity under these conditions as well (King 2004).

The best examples of success in breeding for crop tolerance to flooding are found in rice. Most rice cultivars cannot tolerate flooding for more than 1 week (International Rice Research Institute 2012). However, breeders at the International Rice Research Institute (IRRI) identified a class of ethylene-response-factor-like genes that contribute to flooding tolerance in an Indian rice variety. Three genes, *Sub1A*, *Sub1B*, and *Sub1C*, were found to contribute to flooding tolerance. Of these genes, *Sub1A* was the most important factor contributing to submergence tolerance. Physiological studies showed that rice varieties with *Sub1A-1* overproduce the plant hormone ethylene when submerged. Ethylene accumulation delays cytokine-mediated senescence and promotes dormancy during submergence. Rice varieties containing *Sub1A-1* have exhibited a 1–3-ton yield advantage compared with controls following a 10–15-day submergence period. Several important varieties with submergence tolerance have been released, including *Swarna Sub1* in India, *Samba Mahsuri* in Bangladesh, and *IR64-Sub1* in the Philippines (Kenong et al. 2006; International Rice Research Institute 2012; Jung et al. 2010).

2.05.3.3 Salinity Tolerance

Millions of hectares of land in Africa and Asia are characterized as having highly saline soils that are not suitable for agricultural production (Kundzewicz et al. 2008; Sallemul et al. 2004). To address these problems, plant breeders are developing crop varieties with increased tolerance to saline soils (International Rice Research Institute 2012; Thomson et al. 2010). The problem of saline soils is common in many rice-producing areas. Researchers at the IRRI were among the first to discover regions of the rice genome associated with increased salt tolerance. These regions of the genome are classified as *Saltol*. Unlike *Sub1A*, a single gene controlling tolerance to submergence, multiple *Saltol* loci are required to confer salt tolerance. Although polygenic inheritance complicates the engineering of rice for salt tolerance, recent plant breeding efforts have generated rice varieties that are able to cope with salt stresses at the seedling and reproductive growth stages. Furthermore, salt tolerance combined with *Sub1A* for submergence tolerance has been shown to be a powerful technology for developing varieties of rice for flood-prone, saline soils. To date, more than 100 salinity-tolerant rice varieties have been developed for rice production in salt-contaminated regions around the world (International Rice Research Institute 2012).

2.05.3.4 Nitrogen Use Efficiency

Nitrogen fertility management and availability in the soil may be negatively impacted by climate variability as temperatures rise. Environments with soil surface temperatures near or above 40 °C exhibit greater release of soil nitrogen through volatilization and thus leave less nitrogen for plant assimilation (McCalley and Sparks 2009). To address these issues, plant breeders are faced with the challenge of developing crops with greater nitrogen use efficiency (NUE).

Plant breeding to improve NUE is still in early stages of development, but some advancements have been made in this area. The Monsanto Company and BASF are examining biochemical and physiological mechanisms that might be engineered to improve nitrogen use, including enhanced nitrogen uptake and transport, improved nitrogen assimilation, enhanced protein synthesis, improved photosynthesis, improved general stress response, and pathway regulation. However, the genetic mechanisms for enhancing these traits are still poorly understood (Moose and Below 2009; Monsanto Company 2012b). Pioneer Hi-Bred also is conducting research to examine the development of nitrogen use-efficient hybrids with anticipated release of adapted cultivars later this decade. Arcadia Biosciences has developed a transgenic technology for improving NUE based on an alanine aminotransferase (*AlaAT*) gene from barley (*Hordeum vulgare*) licensed from the University of Alberta. The gene has been transformed into rice and canola and was shown to catalyze a reversible transamination reaction in the nitrogen assimilation pathway. Preliminary results from testing show promise for this technology (Arcadia Biosciences 2012; Good et al. 2007).

2.05.3.5 Tolerance to Elevated Daytime and Nighttime Temperatures

Drought and heat stresses often occur at the same time because of the integrated nature of these stresses in drought environments. However, drought is defined as a deficit of rainfall, whereas heat stress is defined as an increase in temperature beyond a threshold level for a period of time sufficient to cause irreversible damage to plant growth and development (Wahid et al. 2005). Plant breeding for heat-stress tolerance in crop plants has lagged behind other abiotic stress tolerance research. Investigations into the genetic mechanisms influencing heat stress responses are underway, but few heat-tolerant cultivars are known. In maize, CIMMYT is conducting a program to screen for genetic tolerance to heat stresses. An extensive screen of lines developed for drought-prone environments in Latin America and Africa indicated that very few of these lines combine heat and drought tolerance traits. Heat and drought stress tolerance were poorly correlated, suggesting that heat and drought tolerance are controlled by different genetic mechanisms. As genetic sources of high-temperature tolerance are identified, it is hoped that inheritance studies will reveal a genetic architecture that can be manipulated to enhance crop productivity in a range of stressful environments (Zaidi and Cairns 2011).

2.05.4 Challenges of Breeding for Climate Variability

Climate effects and associated environmental vulnerabilities appear in multiple forms. Examples of multiple environmental stresses include excess heat, flooding, drought, and increased salinity of soils. Increased frequency of these stresses will negatively affect crop yields beyond the impacts of changes in mean temperature and precipitation and increase the probability that crop production in future environments will be challenged by multiple and variable stresses from year to year. Agriculture will not have the luxury of engineering future crop varieties with tolerances to individual abiotic stress factors associated with climatic factors. Plant breeders are faced with the challenge of integrating, or ‘stacking,’ multiple abiotic stress tolerance traits or factors into each new cultivar to provide tolerance to a broad spectrum of adverse climate conditions. This will be challenging because efforts to stack multiple genes into a single elite cultivar require both the time for the necessary breeding cycles as well as knowledge and understanding of how traits interact and can be combined to maximize productivity. Plant researchers and breeders have made considerable gains in our understanding of these traits, but greater research investments are needed to make progress in understanding the genetic resources, mechanisms, and pathways needed to engineer and adapt crop plants for the range of climate conditions they could face in the coming decades.

2.06.1 Introduction

Wheat is a major cereal crop in the world and shares about 21% of the global food production. Based on the average data from 2007 to 2009, the global wheat area is 221.7 million ha, with average yield of 2977 kg ha^{-1}, and production of 660 million tonnes. It is a major source of energy in human diet because its protein content is higher than almost all other cereals. It is the most widespread cereal in terms of planting area. Bread wheat (*Triticum aestivum*) accounts for more than 90% of global production and it is grown on a substantial scale (over 100 000 ha) in more than 70 countries on 5 continents. It is mainly used to make bread including steamed bread, noodles, cookies, cakes, and breakfast cereals. Wheat can be classified as winter and spring type, based on the requirement of vernalization. Spring and winter bread wheats share around 70 and 30%, respectively. Durum wheat (*Triticum durum*) accounts for about 5% of global wheat production and is produced mainly in North Africa and Western Asia (35%), North America (35%), and EU (30%). Most durum wheat is spring type, and it is used to produce semolina, pasta, and cracked wheat products such as couscous or bulgur. About 66% of global wheat production is utilized for food, and the remaining 34% for feed and other purpose. Demand of wheat for human and feed consumption in developing countries in 2020 is expected to increase at 1.6 and 2.6% per year, respectively. The global average wheat yield will have to increase during the next 25 years from 2.6 to 3.5 t ha^{-1} (Dixon et al. 2009). Other reports indicate that demand for wheat in developing countries is projected to increase by 60% by 2050 (Rosegrant and Agcaoili 2010). Therefore, increasing wheat productivity is crucial for food and feed security, particularly in the developing countries.

Climate is a major issue in agricultural systems including cereal production. For example, after a 10-year drought, Australia experienced catastrophic floods during fall 2010 and winter 2011, leading to loss of an estimated $6 billion in grain harvest. Estimates of the possible impacts of changes in climate on crop production are inconclusive and model-dependent (Tubiello et al. 2000).

Increased temperatures, major alternations in precipitation patterns, and atmospheric CO_2 concentration, are most important for wheat production. Since 1980, global wheat and maize production have declined by 5.5 and 3.8%, respectively, but with less of a change in rice and soybean **Table 1**. Regional

Table 1 Median estimates of global impacts of temperature and precipitation trends on yield, 1980–2008

Crop	*Impact of temperature (%)*	*Impact of precipitation (%)*	*Subtotal*	*Impact of CO_2 (%)*	*Total*
Maize	−3.1	−0.7	−3.8	0.0	−3.8
Rice	0.1	−0.2	−0.1	3.0	2.9
Wheat	−4.9	−0.6	−5.5	3.0	−2.5
Soybean	−0.8	−0.9	−1.7	3.0	1.3

Data source: Lobell, D. B., W. Schlenker, and J. Costa-Roberts, 2011: Climate trends and global crop production since 1980. *Science*, **5** May 2011/ 10.1126/science.1204531

differences are also observed in Table 2 (Lobell et al. 2011). Therefore, much more attention must be given to understanding the effects of climate on wheat production, so adaptive measures can be taken to ensure global wheat supply in the future. The objective of this chapter is to summarize the impacts of climate on wheat production globally, with a focus on China and India, the first and second largest wheat producers, respectively.

2.06.2 Climate across Wheat Megaenvironments

2.06.2.1 Impact of Increasing Temperature on Wheat Production

Wheat is generally sensitive to temperature increase, which can hasten crop development and shorten grain filling period thus potentially reducing yield, but actual effects are highly dependent on background ambient temperature, which can be associated with geographic location and wheat type (winter or spring type), stage development, and variety.

Data from Australia and Argentina indicated that time from sowing to maturity was reduced up to 0.3 day $year^{-1}$ and time to flowering accounted for most of the variation in time to maturity; and the duration of the postflowering phase was largely unchanged (Victor and Monzon 2006). For spring wheat in a tropical or subtropical environment such as in the Indo-Ganetic Plains of India, increasing temperature would significantly reduce crop season and decrease yield. For winter and facultative wheats in temperate region such as in the Yellow and Huai Valleys of China, increasing temperature has allowed the delayed planting of wheat, reduction of winter-kill, early development in spring, early heading, and slight advance of maturity, thus positive effects on yield could be expected. However, for both environments, heat shock day (temperature over 30 °C) during grain filling period can severely reduce grain yield, largely owing to the reduction of the grain filling period. Temperature increases could reduce wheat in the developing world by 20–30% (Easterling et al. 2007; Lobell et al. 2008; Rosegrant and Agcaoili 2010). Based on the data from 1980 to 2008, the impact of temperature trends to global wheat production is −4.9%, much higher than that for precipitation (−0.6%), although the assumed impact of CO_2 concentration is also higher (+3.0%) (Lobell et al. 2011). Therefore, rising temperature is the most important factor limiting wheat production.

2.06.2.2 Impact of Change in Precipitation Patterns on Wheat Production

Rainfed agriculture depends heavily on rainfall patterns, and precipitation changes may lead to severe droughts in some places and water logging in others (Lobell et al. 2008). Based on the data from 1980 to 2008, the impact of precipitation for global wheat production is −0.6%, but varied in different countries as presented in Table 2 (Lobell et al. 2011). The impact of reduced water availability on rainfed wheat systems is presented in Section 2.06.2.4. Because of the shortage of water, irrigation for wheat production in northern parts of the Yellow and Huai Valleys in China has been reduced from 4–5 to 2–3 times. Occurrence of continuous droughts in China in 2009 and 2011 has significantly reduced wheat production; during the last few years, severe droughts also occurred in Australia, Russia, and EU countries.

2.06.2.3 Impact of Elevated CO_2 on Wheat Production

Based on the IPCC (2007) report, CO_2 has increased from around 280 ppm in the preindustrial era to around 380 ppm in 2005. Apart from positive radiative forcing and resulting surface warming, increasing CO_2 concentration has the potential to increase plant growth and yield in all environments, primarily caused by increased photosynthesis, with greater benefits for C_3 crops such as wheat. Kimball et al. (2002) reported a 10–20% wheat yield increase at 550 ppm

Table 2 Estimated impact of temperature and precipitation trends from 1980 to 2008 on wheat production in five countries

Country	*Impact of temperature trend (%)*	*Impact of precipitation trend (%)*	*Impact of CO_2 trend (%)*	*Total*
China	−2.2	−0.2	3.0	0.7
India	−3.7	−1.8	3.0	−2.5
United States	0.9	0.0	3.0	3.9
Russia	−13.7	−0.5	3.0	−11.3
France	−5.0	0.6	3.0	−1.4
Global	−4.9	−0.6	3.0	−2.5

Data Source: Lobell, D. B., W. Schlenker, and J. Costa-Roberts, 2011: Climate trends and global crop production since 1980. *Science*, **5** May 2011/ 10.1126/science.1204531.

CO_2 depending on nitrogen and water availability. Based on the review of 50 studies on this subject, Amthor (2001) concluded that elevated CO_2 would have a positive impact on yield, but varying with the availability of water, nutrients, and temperature. Leakey et al. (2009) reviewed the six lessons learned from FACE (Free-Air CO_2 Enrichment) regarding the elevated CO_2 effects on plant carbon, nitrogen, and water relations. Controlled laboratory and field chambers have provided an immense database on plant response to rising CO_2 and more importantly, insight into potential mechanisms of response. FACE, which allows treatment of plants under field conditions at a realistic scale, has provided an important reality check. Overwhelmingly, this has shown that data from laboratory and chamber experiments systematically overestimate the yield of major food crops (Leakey et al. 2009).

2.06.2.4 Impact of Climate across Wheat Megaenvironments

The International Maize and Wheat Improvement Center (CIMMYT) has globally defined 12 wheat megaenvironments involving spring wheat (ME1–ME6), facultative wheat (ME7–ME9), and winter wheat (ME10–ME12). A megaenvironment is defined as a broad, not necessarily contiguous, area, occurring in more than one country and frequently transcontinental, defined by similar biotic and abiotic stresses, cropping system requirements, consumer preferences, and, for convenience, by volume of production (Rajaram et al. 1995). Hodson and White (2009) have given an overall review regarding the impact of plausible climate scenarios on future wheat production although the analysis on winter wheat is relatively weak in comparison with spring wheat; therefore, most of the information presented below is derived from their publication, although recent available information is added as necessary.

As indicated in Table 3, for spring wheat from ME1 to ME5, rising temperature would have a negative effect on yield; however, it would have a positive effect on yield for spring wheat in ME6 and winter wheat from ME10 to ME12. Its effect on facultative wheat from ME7 to ME9 is uncertain although observations from China are generally positive.

Effect of changing precipitation is more complex. Reduced water availability would have a negative effect on yield in irrigated environments and rainfed environments such as in ME1, ME2A, ME4A and ME4B, ME7, ME9, ME10, and ME12, through reduced irrigation or evolving from partial irrigation to rainfall crop production. However, it may have uncertain effects on yield in high rainfall environments such as in ME2B, ME3, ME4C, ME8, and ME11.

2.06.2.5 Impact of Climate on Wheat Diseases and Pests

Changes in atmospheric composition and the rest of the climate system would include temperature, rainfall, and humidity, which would affect the economic importance, geographical distribution, and management of diseases effecting crop production. Climate affects the effectiveness of host plant resistance and pathology fitness because of modified host and pathology, and host–pathology interaction. Wheat scab and wheat stripe rust severity in China and stem rust in the United States have been linked to the El Niño-Southern Oscillation Index (Scherm and Yang 1995). New stem rust pathotype 'Ug99' can pose significant threats to global wheat production (McIntosh and Pretorius 2011). Wheat blast, caused by a fungus *Magnaporthe grisea*, first identified in Brazil in 1985, is an emerging disease in South America. The disease has become a serious threat to wheat production in the tropic and subtropic regions, including Brazil, Argentina, Bolivia, and Paraguay. Climate is the key factor to the disease development, and hot and humid climate favor the development of wheat blast (Kohli et al. 2010).

Models predicting the geographical distribution of host plants and their diseases as a function of climate can serve as a guide to possible future disease prevalence. However, only four diseases of field crops have been studied under realistic field conditions in FACE facilities, and the effects of climate on wheat yellow rust were reported by Chakraborty et al. (2011). The effectiveness of resistance in wheat varieties could change under a changed local and regional climate and/or resistance maybe overcome quickly by new pathotypes. For wheat leaf rust, obligate parasitism is generally inhibited by elevated O_3; infection by facultative pathogens could increase, decrease, or remain unchanged (Tiedemann and Firsching 2000). Under the ambient (380 ppm) and elevated CO_2 (820 ppm) concentrations, there are no interaction between CO_2 concentration and level of resistance, and the effectiveness of partial resistance in variety Janz was not changed (Chakraborty et al. 2011). It is likely that rusts of wheat would be able to adapt to increased temperature as reported for yellow rust in the eastern United States (Markell and Milus 2008). In wheat, the expression of many genes for resistance to leaf rust, stripe rust, and stem rust is influenced by temperature and/or plant development stage. Some resistance may become less effective at high temperature. For example, *Yr18* is known to be temperature mediated and become more effective at higher temperature. Rust reaction of varieties with *Sr15* can change from resistance at 15 °C to nearly fully susceptible at 20 °C. Much more work is needed to understand the performance of partial resistance genes under rising CO_2 and temperature levels. Australia and the United States have increased emphasis on durable resistance based on additive effects of partial resistance genes.

2.06.3 Climate and Wheat Production in China

2.06.3.1 Wheat Ecological Zones

China is the largest wheat producer and consumer in the world. At present, around 23.5 million ha of wheat are harvested annually, with a production of about 110 million tonnes. Chinese wheat area has been divided into 10 major agro-ecological zones as presented in Figure 1, based on wheat types, varietal reactions to temperature, moisture, biotic and abiotic stress, and wheat growing seasons (He et al. 2010). On the basis of sowing dates, autumn-sown wheat accounts for more than 95% of production and acreage. Winter and facultative wheat, sown in the North China Plain (Zone I) and the Yellow and Huai River Valleys (Zone II), contribute around 70% of the production. Autumn-sown, spring habit wheat, planted in both the Middle and Low Yangtze Valleys (III) and the southwestern China (Zone IV), contributed around 25% of production. Spring-sown spring wheat is mostly planted in northeastern and northwestern China (Zones VI, VII, and VIII)

Table 3 Suggested impacts on wheat production in different megaenvironments (MEs) from a set of climate metrics

Mega-environment	*Representative sites*	*Concerns/opportunities*
Spring wheat		
ME1: Favorable, irrigated, low rainfall	Gangetic Valley, India Indus Valley, Pakistan Nile Valley, Egypt Yaqui Valley, Mexico	N – Rising temperature result in large areas evolving to ME5 N – Reduced precipitation in subtropical regions restricts irrigation P – Reduced irrigation due to impact of elevated CO_2 on water use efficiency
ME2A: Highland, summer rain	Kulumsa, Ethiopia	N – Rising temperature result in large areas evolving to ME5
ME2B: Lowland, winter rain	Toluca, Mexico Izmir, Turkey Pregamino, Argentina	N – Reduced precipitation result in areas evolving to ME4 N – Rising temperature result in large areas evolving to ME5 U – Changes in precipitation patterns in areas will have variable effects
ME3: High rainfall, acid soil	Passo Fundo, Brazil Mpika, Zambia	N – Rising temperature result in large areas evolving to ME5 N – Rising temperature result in large areas evolving to ME5
ME4: Low rainfall	See below	N – Rising temperatures exacerbates water deficits, either further reducing yield or making production uneconomical P – Reduced water deficits through impact of elevated CO_2 on water use efficiency
ME4A: Winter rain or Mediterranean type climate	Aleppo, Syria Settat, Morocco	N – Rising temperature result in large areas evolving to ME5 N – Changes in precipitation patterns likely to increase drought risk
ME4B: Winter drought or Southern Cone type rainfall	Marcos Juarez, Argentina	N – Rising temperature result in large areas evolving to ME5 N – Changes in precipitation patterns likely to increase drought risk
ME4C: Stored moisture	Dharwar, India	N – Rising temperature result in large areas evolving to ME5 U – Changes in precipitation patterns in areas will have variable effects
ME5: Warm, humid, or dry	Joydebpur, Bangladesh Encarnacion, Paraguay Kano, Nigeria Wad Medani, Sudan	N – Rising temperature result in large areas becoming unsuitable for wheat N – Increasing biotic stress U – Elevated CO_2 may increase water use efficiency, but the same mechanism implies increased canopy temperature, which likely would exacerbate heat stress
ME6: High latitude (>45 °N or S)	Urumqi, Xinjiang, China Astana, Kazakhstan Harbin, Heilongjiang, China	P – Rising temperatures lengthen growing season and permit marginal areas to become productive P – Reduced risk of winter-kill allows conversion to more productive winter wheat
Facultative wheat		
ME7: Favorable, moderate cold, irrigated	Zhenzhou, Henan, China	U – Reduced cold stress allows growing spring wheat, possible reducing yield potential, but shortening growing season P – Reduced irrigation due to impacts of elevated CO_2 on water use efficiency
ME8: High rainfall (>500 mm), moderate cold	Diyarbakir, Turkey Vernon, Texas	U – Reduced cold stress allows growing spring wheat, possible reducing yield potential, but shortening growing season U – Changes in precipitation patterns in areas will have variable effects P – Reduced water deficit through impact of elevated CO_2 on water use efficiency
Winter wheat		
ME10: Favorable, cold, irrigated	Beijing, China	P – Warmer winters reduced severity of winter-kill, increasing yields N – Warmer spring and summer hasten grain-filling P – Reduced irrigations due to impacts of elevated CO_2 on water use efficiency
ME11: High rainfall, cold	Odessa, Ukraine Krasnodar, Russia	P – Warmer winters reduced severity of winter-kill
ME12: Semi-arid, low rainfall, cold	Ankara, Turkey Manhattan, Kansas	P – Warmer winters reduced severity of winter-kill P – Reduced water deficit through impact of elevated CO_2 on water use efficiency N – Increased insect problems

P = positive impact, N = negative, and U = uncertain.

and makes up 5% of the production. More than 70% of Chinese wheat is produced in five provinces: Henan, Shandong, Hebei, Anhui, and Jiangsu. Detailed information on Chinese wheat production was reviewed by He et al. (2010).

2.06.3.2 Wheat Phenology and Cropping System

Annual mean temperature in China showed an increasing trend from 1905 to 2011; the first significant increasing period was from 1930 to 1945, and the second significant increase was observed since 1990. A warming trend was also observed in the major wheat area from 1961 to 2006. The increase of average temperature, maximum temperature, and minimum temperature in the five major wheat provinces (Henan, Shandong, Hebei, Anhui, and Jiangsu) are 0.53–0.75 °C per decade, 0.37–0.70 °C per decade, and 0.58–0.80 °C per decade, respectively (W. Xiong, CAAS, personal communication). In the Yellow and Huai Valleys, which produce around 70% of Chinese wheat, there has been a significant decrease in sunshine hours and radiation since 1961 owing to increase aerosol in the atmosphere, a trend of rising air temperature since 1980s, a trend of decreasing annual precipitation in the northern part, and increasing precipitation in the southeast part of the region. These climatic trends led to a shortened growing period for wheat and an extended growing season for maize under the wheat/maize rotation system (Liu et al. 2010; Tao et al. 2006). However, the impact on wheat phenology and yield was varied because of the different targeting regions and various methods employed. For example, from 1981 to 2000 the maximum and minimum temperatures in Zhengzhou, located in the Yellow and Huai Valleys, in winter (December–February) were significantly increased by 0.95 and 0.92 °C per decade, respectively; whereas in spring (March–May) the minimum temperatures also increased by 0.74 °C per decade, but the maximum temperature did not increase significantly. Wheat planting, anthesis, and maturity dates in Zhengzhou did not occur significantly earlier, and wheat yields did not decrease significantly; however, planting, anthesis, and maturity dates at Tianshui, also located

Data source: L. Zhang (2011, unpublished data).

in the Yellow and Huai Valleys, occurred earlier (Tao et al. 2006). Liu et al. (2010) reported the contributions of climate and crop variations to wheat production in three major locations (Luancheng in Hebei province, and Zhengzhou and Nanyang in Henan province). Warming mainly occurred during the vegetative growth stage (preanthesis), whereas there was a cooling trend or no significant change in temperature during the postanthesis stage. If varietal effects were excluded, warming during vegetative stage would lead to a negative reduction in wheat yield. However, adaptation of new varieties (reflected in reduced requirement for vernalization and photoperiod sensitivity) was able to compensate for the negative impact of climatic. The combined effect led to increased wheat yield at Zhengzhou and Luancheng and stabilized yield at Nanyang. In the North China Plain (Zone I), Wang et al. (2008) found a clear trend of warming from 1981 to 2004 in Xifeng (34°44′N, 107°38′E, 1420 m), leading to the earliness of pseudo-stem elongation, booting, anthesis, and maturity by 13.2, 9.8, 11.0, and 10.8 days, respectively. The growth period from seedling emergence to stem elongation shortened 16.1 days, but the growth period from anthesis to milk prolonged 8.2 days. Li et al. (2010) reported that each 1 °C rise in daily mean temperature would reduce the averaged wheat yield in China by 4.6–5.7%, largely caused by the reduction of growth duration. However, Chavas et al. (2009) predicated that aggregate potential productivity of autumn-sown wheat increased by 24.9% under the enhanced CO_2 fertilization effect, based on the Environmental Policy Integrated Climate (EPIC) agro-ecosystem simulation model. Unfortunately, only very few sites located in minor wheat areas were included in the modeling, thus much more work is still needed to understand the impact of climate on Chinese wheat production.

In summary, for winter and facultative wheat in Zones I and II, temperature increases in autumn and improved varieties would allow late wheat planting; a temperature increase in the winter and in the spring benefits the early development for vegetative phase, thus early heading is observed; and the nonsignificant increase or even slight cooling during grain filling period basically maintains the yield, and maturity was slightly advanced, thus allowing the early planting of maize under the wheat/maize rotation system. This has been confirmed by the control trials under warmed at nighttime and unwarmed plots in the Yellow and Huai Valleys conducted by the Nanjing Agricultural University as presented in Table 4 (L. Zhang 2011, unpublished data). It indicated that warmer temperature would benefit wheat production, largely because of the early anthesis, slight advance of maturity, increased grain number per spike, and thousand kernel weight.

Comparison of wheat phenology in representative locations in China between 1980 and 2011 is shown in Table 5. In general, four different patterns have been observed in various regions. (1) Planting date for winter and facultative wheats in Zone I and northern parts of Zone II, including provinces of Shandong and Hebei, was delayed around 7–10 days owing to the temperature increase and extension of new variety conferring tolerance to late sowing, and heading date was advanced around 7 days; however, maturity remains basically unchanged or slightly advanced, thus increased yield was obtained through the extended grain filling duration, which is around 7 days. At the same time, irrigation has been reduced from 4–5 to 2–3 times because of the decline of irrigation water. Direct sowing of maize after harvesting of wheat and the delayed planting of wheat have made the popularity of the wheat/maize rotation system, which has basically replaced the three crops per 2 years system (wheat–maize interplanting or relaying and then cotton) or wheat–maize relay system (maize is sowed around 2–3 weeks before harvest of wheat). (2) Sowing date in Henan province located in the south part of Zone II was also delayed 7–10 days, but heading and maturity remained basically unchanged; therefore, no significant change in the wheat/maize rotation system was observed. (3) Cropping season and rotation system in Zones III and IV remains basically unchanged, although zero tillage is significantly increased to allow the early planting of wheat in the Middle and Low Yangtze Valleys (Zone III) and southwestern China (Zone IV). But significant variation in heading ranging from 6 March to 25 March and

Data sources: Collected from senior wheat scientists at each location by Zhonghu He, 1980, 2009 are assumed to be representative of 30 years ago and present.

maturity ranging from 2 May to 15 May was observed in the same location owing to the temperature fluctuation. (4) Planting dates in most spring wheat areas (Zones VI, VII, and VIII) were also advanced around 7 days largely because of the temperature increase in late February or early March, and maturity was also slightly advanced, thus wheat–maize relay has become the dominant system at present.

2.06.3.3 Planting Winter Wheat in the Spring Wheat Region

Winter wheat is more attractive to farmers in China even in the traditional spring wheat area, largely because of its early maturity (thus allows the planting of vegetables and other crops), high yield potential (at least 10–20% higher than spring wheat), and better quality owing to the avoidance of preharvest sprouting. Therefore, the Chinese Ministry of Agriculture initiated a coordinated winter wheat program targeting the traditional spring wheat area, including the provinces of Liaoning, Heilongjiang, Inner Mongolia, Gansu, and Ningxia in the early 1990s, mainly through screening winter wheat varieties from Russia and Canada and modification of cropping management. However, no significant progress has been achieved in most institutes because of the shortage of varieties conferring strong cold resistance and poor snow coverage. After 20 years of continuous efforts, winter wheat has been successfully replaced by spring wheat in Ningxia and part of Gansu and Qinghai provinces. The success of winter wheat is largely due to the benefits of temperature increases and the development of improved winter wheat varieties through crossing local varieties with elite introductions from other countries. Scientists and extension staff are also testing winter wheat in Inner Mongolia and Liaoning at present. Therefore, it is very likely that winter wheat is gradually replacing spring wheat in China.

Spring wheat is a traditional crop in the irrigated area of Ningxia (Zone VIII) where irrigation is provided from the Yellow River, with latitude ranging from 35° to 39° N, and altitude 1100–3556 masl. The basic cropping system includes spring wheat-rice-spring wheat in 2 years and spring wheat–maize relaying in 1 year. Spring wheat is planting from late February to the first week of March, and harvested around 10 July. Winter wheat is planted from 20 September to 10 October, and harvested from 25 June to 30 June, with yield advantage of 2.0–2.5 t ha^{-1} in comparison with spring wheat. With the replacement of spring wheat by winter wheat, maize yield also increased around 750 kg ha^{-1} owing to the early harvesting of winter wheat. More importantly, a new cropping system, that is, winter wheat–forage maize rotation, is well developed and extended. Much more income is generated from the cattle industry by the planting of forage maize. With the release of winter wheat varieties Ningdong 10 and Ningdong 11, the winter wheat area reached 34 500 ha in 2010 and 400 000 ha in 2011, sharing 40 and 50% of the local wheat area, respectively. Zhongmai 175, a winter wheat variety released in North China Plain, also covers around 13 000 ha in the spring wheat area of Gansu and Qinghai provinces. A breeding and germplasm testing program will be needed to support the winter wheat development in Ningxia, Gansu, Qinghai, and Inner Mongolia, although elite germplasm from the Chinese Academy of Agricultural Science station in Beijing perform quite well at present. Efforts should be encouraged to also test winter wheat in Heilongjiang province (Zone VI).

2.06.3.4 Future Perspective

As indicated before, positive benefits of climate were generally observed for Chinese wheat production in the last 30 years, largely due to the delayed sowing of winter and facultative wheat and early sowing of spring wheat. However, negative impact of climate was also significant, including the frequent occurrence of drought, the unpredictable extreme temperature in the winter and the spring, and the increased loss from diseases. For example, more than 100 days of continuous droughts were recorded in 2008–09 and 2010–11 wheat seasons. The arrival of cold temperature in early November in 2009 and slow increase of temperature in the spring of 2010 delayed the wheat season 7–10 days in 2009–10 compared with the average over the last 10 years; thus significant yield loss was observed and also delayed the planting and harvest of maize.

Yellow rust were the major wheat disease, but it is much less significant in Zones I and II at present. In addition to powdery mildew, Fusarium head blight (*Gibberella zeae*), sharp eye spot (*Rhizoctonia cerealis*), and take-all (*Gaeumannomyces graminis var. tritici*) have been well established in Zone II. For Fusarium head blight, acceptable level of resistance is achieved in the autumn-sown spring wheat region (Zones III and IV), but much more efforts are needed in the winter and facultative wheat region (Zone II). It is very likely that damage of Fusarium head blight is becoming more serious than before, largely because of climate and the dominant wheat/maize rotation system. Very little progress has been made in improving resistance to sharp eye spot because of the lack of an effective method for screening resistance and the shortage of resistance in bread wheat.

Because of the temperature fluctuations, a variety with broad adaptation is needed. A favorable genotype under current climate is characterized by slow development before heading (insensitive to photoperiod and temperature) and fast grain filling rate with resistance to high temperature during the grain filling period. High yield potential must be combined with resistance to lodging and tolerance to drought. Therefore, multilocation testing is encouraged in breeding programs.

Much more effort is need to improve crop management, including the management of maize residue in the Yellow and Huai Valleys, so planting quality can be improved. This will significantly reduce seedling rate and winter-kill. Improvement of water and fertilizer use efficiency is also crucially important; this will reduce production inputs and protect the environment.

2.06.4 Climate and Wheat Production in India

2.06.4.1 Wheat Production in India

India is the second largest wheat producer and consumer in the world, after China. Wheat production has increased substantially in the past, from 12.3 million tonnes in 1965 to a record 84.5 million tonnes in 2011 with an area of 29.0 million ha. However, over the last 10 years there have been no significant increases in production, as indicated in Table 6. Therefore, further increase of wheat productivity is a significant challenge.

Wheat area in India is divided into six agro-climatic zones as indicated in Figure 2, but the Indo-Gangetic Plains comprising the Northwestern Plains Zone and Northeastern Plains Zone with high yielding, well irrigated and fertilized conditions share more than 70% of wheat area and produce around 85% of national production. The Central Zone characterized with higher temperatures and less water availability shares around 10% of production. Wheat in northern India is planted in October/November, after rice harvest. Wheat approaches the anthesis and grain filling period in February and March; mean temperature and the frequency of heat days (temperature >30 °C) start to increase substantially in March and April. Therefore, it is crucial that wheat is timely planted, around mid-October, and the anthesis and grain filling period are completed before rapid temperature increase in March and April.

Table 6 Wheat area, average yield, and production in India, 2000–09

Year	*Area (M ha)*	*Average yield (kg ha^{-1})*	*Production (M tonnes)*
2000	27.5	2778	76.4
2001	25.7	2712	69.7
2002	26.4	2758	72.8
2003	25.2	2611	65.8
2004	26.6	2714	72.2
2005	26.4	2591	68.4
2006	26.5	2619	69.4
2007	27.8	2727	75.8
2008	28.0	2807	78.6
2009	27.8	2899	80.6
2010	27.9	2800	80.7
2011	29.0	2900	84.5

2.06.4.2 Impacts of Increased Temperature on Wheat Production

Heat and drought are the two major abiotic stresses, and about 13.5 million ha sharing 50% of the wheat area is considered to be prone to heat stress. However, there is much more information available on the effect of increased temperature and heat shock days (temperature over 30 °C) to production than water availability.

Average annual temperatures in India have increased by 0.5 °C over the past 100 years. Based on the calculations by Aggarwal et al. (2009), each 1 °C rise in regional mean temperature would result in an annual wheat yield loss of 6.6 million tonnes in India. Nelson et al. (2009) hypothesized that rainfed wheat yields in South Asia will decline by around 44% by 2050 owing to alterations in regional climate. Ortiz et al. (2008) reported that by 2050, as a result of possible climate effects in the Indo-Gangetic Plains, currently part of the favorable, high yielding potential, irrigated, low rainfall wheat production megaenvironment (ME1), as much as 51% of its area, might be reclassified as a heat-stressed, irrigated, short season production megaenvironment (ME5).

High temperatures potentially damage wheat throughout the growing season, but the overall impact on yield varies according to their incidence and stages of crop development (Singh 2009). High temperatures in the early season from November to December were reported to have accelerated crop phonological development and as a result reduced yield potential. High temperatures (over 30 °C) can be more damaging during the anthesis and grain filling periods, resulting in significantly reduced yield (Rane and Nagarajan 2004). In many of the dry environments suffering from severe heat stress during grain filling, it has been shown that the enzyme

soluble starch synthase in wheat appears to be rate-limiting at temperatures in excess of 20 °C (Keeling et al. 1994). The grain filling of wheat is seriously impaired by heat stress, owing to reductions in current leaf and ear photosynthesis at high temperatures.

Increasing temperatures also would have indirect effects on the incidence of crop diseases and pests, and to grain quality and nutritional value. Both pest and disease populations are significantly affected by temperature, humidity, and elevated carbon dioxide levels (Aggarwal 2008). Singh (2009) reported on the influence of temperature on the incidence of the three rust diseases of wheat – yellow, leaf, and stem rust. In addition, leaf spots and blights (*Helminthosporium*) tend to be more prevalent under higher growing season temperatures. Singh (2009) also postulated that Fusarium head blight incidence could increase in the future. It is not possible to be more definite on these indirect effects of changed climate, but these are important areas for further study.

Water is the other factor influencing wheat production in India. Preseason (October–November) rainfall has generally declined in northern India in recent years, with a more significant decline in North West Wheat Zone. Ground water tables are declining at the rate of 33 cm year^{-1}; losses have mainly occurred in northwest India, whereas there have been increases in central India. Gross per capita water availability is predicted to decline from about 1820 m^3 in 2001 to as low as about 1140 m^3 $year^{-1}$ in 2050 (IPCC 2007). Therefore, an increase of annual temperature and number of heat events, and declined water availability are clearly a risk to future wheat production in India.

2.06.4.3 Future Perspective

Recognizing the potentially and significantly negative impact of increasing temperatures and the decline of water available for agricultural production, the Indian Government requested the Food and Agriculture Organization of the United Nations (FAO) to review the impacts of climate on wheat production in India in September 2009. The review team recommended short-term (1–5 years) and short- to medium-term (5–10 years) implementation of adaptation measures that will bolster future food security and at the same time allow Indian wheat growers to remain productive, profitable, and sustainable. They included measures implemented on-farm immediately, research and development activities for immediate investment, other strategic research and development needs, and economic and policy measures for immediate consideration (FAO 2009). The following part is largely summarized from the FAO Report in 2009.

Short-term adaptations include increasing communication and preparing farmers to cope with climate such as promotion of adaptive research and large scale demonstrations in farmers' fields and strengthening capacity of farmers. Extension of heat tolerant varieties, promotion of conservation agriculture technology, and crop diversification were the major recommended technologies. Studies in both India and Mexico have shown that zero-tilled wheat, with crop residues retained, had canopy temperatures 1–2 °C cooler than conventional planting technology, and resultant higher grain yields (Sayre and Govaerts 2009). It will also allow timely planting to avoid heat stress later in the season, reversing soil degradation, and water and diesel fuel savings. Therefore, accelerating the adoption of conservation agriculture (CA)-based integrated cropping management (ICM) packages for wheat-based systems was strongly recommended. Diversification of cropping systems includes enhancement of relay/intercropping systems, promotion of more water efficient crops such as maize and barley, inclusion of legumes in rotations, shifting from long duration rice varieties to medium duration varieties, and allowing more timely planting of wheat.

Short- to medium-term adaptations include development of new wheat varieties with super heat resistance, higher water use efficiency, enhanced disease and pest resistance, and ability to respond to elevated levels of atmospheric CO_2. In order to accelerate the selection and breeding of these new varieties, new molecular approaches will be necessary to achieve the efficiencies and effectiveness desired. Field evaluation for a trait such as heat tolerance and improving water use efficiency has proved difficult, and marker-assisted selection is likely to achieve greater success (Hays et al. 2007; Richards et al. 2010; Mason et al. 2011). Improvement of conservation agriculture-based technologies is also needed, including better varieties and more adaptive and diverse systems. More research is required on understanding genotype and conservation agriculture technology interactions, diversification of wheat-based systems to include a broader range of crops including durum wheat, maize, oilseeds and pulses, and increase water use efficiency.

2.06.5 Conclusion

Much more research is definitely needed to have a clear understanding on the impact of climate on wheat production. It offers great opportunity and challenges for policy makers, farmers, and agricultural scientists. Basically there are two technical approaches to copy with climate, that is, crop management and improved varieties, and various aspects have been reviewed in *Climate Change and Crop Production* (Reynolds 2010). The strategies for developing new cropping systems include use of crop models in decision-making, applying remote sensing and precision agriculture technologies, monitoring crop condition, optimized water use efficiency, and optimize land use (CSSA 2011). Crop diversification including testing and adaptation of new crops and cropping system as recommended for India can maintain relatively good productivity under climate changing conditions; it may also generate high income for small farmers. Conservation agriculture based on minimal soil disturbance, permanent ground cover, and crop rotation has proved to be a powerful technology particularly under rainfed conditions, to reduce soil erosion, increase water use efficiency, early planting of wheat under the rice/wheat rotation system, and increase productivity (Hobbs and Govaerts 2010). Development and adaptation of new varieties that combine high yield potential with enhanced tolerance to high temperature and water use efficiency will be an economical friendly approach for increasing wheat production. Molecular markers assisted selection (MARS) and genetic transformation (Whitford et al. 2010) can play an important role for improving drought and heat tolerance. However, conventional breeding is still the most powerful approach to develop new varieties, and multilocation testing remains the most efficient system to identify varieties with broad adaptation to various geographical locations, and wide ranges of environment and management conditions. The strategies for improving existing varieties and developing new crops include (1) develop new crops; (2) integrate beneficial traits into existing crops through use of germplasm collections, rate datasets, and breeding; (3) use new technologies, image-based measurements, high throughput DNA sequencing, databases, and statistical models; (4) identify crop germplasm that tolerates drought, heat, and water logging; (5) expand field level evaluations of crop germplasm; and (6) employ new tools, techniques, and datasets to accelerate the delivery and release of proven varieties (CSSA 2011). In the long term, research investment and efforts are needed to further understand the physiological, genetic, and molecular basis of adaptation to drought, heat, and biotic stresses from the climate; translate new knowledge into new agricultural systems that integrate genetics and management technologies; and transfer knowledge effectively and make technologies and innovations widely available to increase food production and stability (CSSA 2011).

References 72

Marine capture fisheries are a critical source of high quality protein in many areas around the world, providing a billion people with more than 20% of their animal protein (FAO 2009). Many of the people most dependent on fishery production are in impoverished communities located in small island states, South Asia, Southeast Asia, and Africa (FAO 2007). Globally, overall fishery production from both capture fisheries and aquaculture (144 million tons in 2006) provides nearly 17 kg of fish per capita. These figures give a simple picture of the importance of fisheries for global food security. Fisheries resources, whether in coastal waters or on the high seas, are highly vulnerable to long-term environmental change, including climate change, because production is dependent on the underlying natural system. Climate impacts such as ocean temperature increases can profoundly affect production of natural and cultured stocks including changing growth, reproduction, survival, and other critical life history features of exploited stocks and the ecosystems that they depend upon (FAO 2008; Garcia and Rosenberg 2010).

In the developed world, fisheries are often out of sight and mind, in some sense obscure to a large part of the population. Yet fisheries are the last great hunting and gathering means of food provisioning around the globe and are subject to very different pressures as environmental change occurs, compared to land-based agriculture. Fish and fisheries can change rapidly, and sometimes dramatically, from area to area, in species composition, in the fishermen that have access, and the level of production available. Like all food production, fisheries are completely dependent upon natural systems to support productivity. But unlike land-based agriculture, humans can only directly control fishing activity, not the underlying system that produces the fish. In other words, capture fisheries are still wholly dependent on the natural productivity of the ocean. While aquaculture is increasing rapidly and now accounts for half of the fish production for human consumption globally, it too can only be sustained by natural systems. Aquaculture requires habitat (e.g., circulating water of high quality and the right characteristics), nutrients, feed, and space within natural systems. While culturing alters systems to enhance productivity, very specific conditions are still required for success whether on land or in the sea.

Climate will be a major driver of vulnerability in fisheries in the coming decades, but not the only human-induced driver of change and potential depletion. Both capture fisheries and aquaculture have a history of overexploiting the natural systems upon which they depend. For capture fisheries, overexploitation results in reduced abundance of many species, habitat loss due to the impact of fishing (and other activities), reduced size and value of the fish in the catch, and in some cases fundamental changes in the marine ecosystems supporting fish production (NRC 2006). For aquaculture systems, overexploitation takes a different form, causing loss of habitat due to siting of farms, effluent, disease and other direct environmental impacts, competition for coastal space, and the use of wild caught fish for feed. In both cases, production, if not well managed, increases the vulnerability and reduces the resilience of marine ecosystems to changing conditions (Carpenter et al. 2001; NRC 2006). For example, a well-managed fishery maintains the exploitation rate (proportion of the stock removed by harvesting each year) at levels below that which can, on average, be replaced by natural production each year. In the course of this, the size and age composition of the population have a fairly broad distribution such that the fishery is not strictly dependent upon annual reproduction in each year. But in an overexploited fishery, the harvest becomes increasingly dependent on annual reproduction, and the result is that one year of poorer reproduction can result in major declines in the stock of fish in the ocean. There is no buffering effect of having multiple years of reproduction present in the population, and vulnerability to poor environmental conditions is increased. Similarly, if aquaculture is highly concentrated in one area, the water quality is degraded and disease prevalence is not controlled, then production is vulnerable to poor conditions in any one year, and to new outbreak of disease or other effects.

In contrast, well-managed systems have higher abundance and diversity, and are able to maintain resilience to these kinds of environmental effects with a greater capacity to bounce back from perturbation. In the context of climate impacts, fisheries that are not overexploited can be expected to 'weather' climate variability and change in average conditions better. This is essentially analogous to the portfolio effect often referred to in investment strategies. Having a single investment type, or in the case of a fishery a single resource (e.g., species, age groups), is highly vulnerable to loss due to changing conditions. However, a diversified portfolio is buffered against losses in any one element of the portfolio. Overharvesting effectively reduces the scope of the portfolio of fishery resources, and so is an inherently risky strategy, particularly in the face of a changing climate. Note that this conclusion does not require in-depth knowledge of exactly how any given fish stock in the portfolio will respond to climate. Diversification of investment in the face of uncertainty is a well-known approach to reducing risk, and is directly applicable to sustaining fisheries.

Climatic changes have and will affect ocean and coastal areas in many ways. The most direct are increasing water temperature, rising sea level, and increased acidity of the water (IPCC 2007; Cooley and Doney 2009). In addition, changes in precipitation and runoff of freshwater, land-based sources of sediment and nutrients, changes in severe weather frequency, and intensity are likely to have major impacts. From a fishery and aquaculture perspective, these changes will result in habitat

http://dx.doi.org/10.1016/B978-0-12-384703-4.00214-8

changes for commercially important species of fish and shellfish, and changes in availability of resources to fishing communities (Barange et al. 2010a,b). Habitat changes such as increasing water temperature, changes in coastal nursery areas such as mangroves and salt marshes due to sea level rise, or changes in nutrient dynamics that effect ocean primary productivity will result in changes in fish production – both increases and decreases. In a general sense one might expect fish populations to move poleward and deeper as temperatures increase, to stay within their thermal tolerance ranges. As such, some areas will become more productive for certain species and some less so for those same species (Brander 2007; Cheung 2009). But, it is not as if there are areas of the ocean that are currently not utilized. Distributional changes will undoubtedly not happen in concert as different species will adapt to changing conditions at differing rates, because life history strategies (generation times, growth rates, etc.) differ widely among fish species and populations (Barange and Perry 2009). Predator and prey may adapt at different rates, and new prey or predators may become important in a given ecosystem (Stenseth et al. 2002). Spawning sites take time to be populated and productive for many species, and nursery area proximity to spawning grounds may be greatly different. All of these changes result in great uncertainty in the adaptive capacity of any given stock of fish to changing climatic conditions. Of course, this process has been going on for millions of years as natural populations have adapted to changing environments. Two things are different in the current course of environmental change; observed climatic changes are much more rapid than in the past millennium, and human exploitation and other environmental impacts have altered adaptive capacity of natural populations in multiple ways (Miller et al. 2010).

From simple ecological theory, some species are likely to be favored (with regard to productivity at the population level) by rapid environmental change and others are vulnerable. This of course adds to the uncertainty. Already, some increases in productivity are apparent in sub-Arctic and Arctic areas from temperature increases (Stenevik and Sundby 2007; Brander 2007). But how this is changing food webs in these areas is an open question (Pauly et al. 2000). Other analyses suggest that there will be large-scale depletion of fishery resources in the tropics, but this may be an artifact of our lack of knowledge of the adaptive capacity of tropical species (Cheung 2009). If the temperature tolerances of the current set of commercially important species remain unchanged, then poleward and deeper shifts in distribution will deplete tropical areas that support some important fisheries. In general, it is hard to estimate which species will move in to replace those whose distributions shift. But, nature usually does not leave a vacuum, so again the uncertainly is high. Tropical area fisheries are particularly critical to food security for some of the poorest peoples, so even the potential for large reductions in fishery productivity must be addressed.

Productivity of fish stocks, and potentially aquaculture operations, may additionally change because of physiological responses to warming or other habitat changes. In some cases, faster initial growth, but smaller adult size for some species may result, impacting fishing or culturing operations (e.g., processing, marketability), as well as food web considerations. Aquaculture is an interesting case. Domestication selection for culture stock obviously speeds up the process of adapting to culture conditions (habitat) and market considerations; however, many operations are dependent upon specific strains and adapting to future unknown conditions, to say the least, challenging both technically and from a business perspective. Case in point is the apparent impacts of ocean acidification that are already occurring for some shellfish aquaculture operations in the US Pacific Northwest (J. Buizer, personal communication). Settlement of larvae has been impaired in some cases because of lower pH and selection for more tolerant strains may already be underway. Even though this selection may occur faster than in nature, will it be fast enough for commercial purposes?

In fact, many of the concerns over the impacts of climate on fishery and aquaculture production come down to uncertainty about rates of change. How fast will distributions shift? How quickly will species life histories adjust? How quickly will food webs alter? What will be the time course of change in productivity (both increases and decreases)? These rates are difficult to predict which means that monitoring of fisheries and aquaculture will be increasingly important to avoid loss of resources. The consequences of allowing rapid expansion of fisheries as some stocks extend or shift their range, for example, into Arctic waters, are overexploitation and the loss of real opportunity for food production. From the history of fisheries, it is clear that fishing pressure on a stock can and will expand very rapidly once an opportunity is identified, unless strong regulatory controls are in place (Rosenberg 2003). The result is a rapid increase in catches to unsustainable levels and a decline in the resource, sometimes a real collapse (e.g., Northern cod in Canada in the 1990s, fisheries on seamounts in the 1990s and 2000s), followed by poor or no catches for many years due to the loss of productivity (Garcia 2009).

Similarly, if productivity is declining due to climate effects (at an unknown rate without monitoring), then overexploitation or the loss of adjustment time for the industry will likely result with dislocation of fishermen along with loss of food production. So the need to monitor distributional changes, productivity rates, and habitat changes is crucial for both fisheries and aquaculture, along with a need for strong management controls to ensure sustainability of both the resource and the industries that depend upon them.

Climatic impacts cause increasing stress not only on natural resources, but also on the industries and people that depend upon them, as well as the management systems intended to conserve the resources (Miller et al. 2010). Fishing and aquaculture businesses will struggle to adjust not only to changing resources, but to increasing stress in ocean areas from population shifts, changes in coastal areas that affect coastal access, as well as coastal habitat for fishery or aquaculture resources, the impacts of increasing severe weather events, and the effects of climate on other food resources (Perry et al. 2010). If fishery stocks shift in distribution, then access and costs to reach fishing grounds will change. Sea level rise will change port and landing facility conditions, including vulnerability to natural hazards. And, the loss of availability of other food resources including agricultural production and wild food harvest on land can increase pressure on fisheries, particularly for subsistence or small-scale fishermen.

Large vessels with greater range will certainly have the ability to adjust to changing fish stock distribution patterns.

However, the capability to operate farther afield is not a full measure of adaptive capacity for fishing businesses, since larger vessels require greater catches, and therefore stock productivity (or a larger share of the catch that is available), than smaller vessels. It is not easy to predict how the availability of stocks will affect allocations between different sizes of vessels, but it is clear that there are likely to be changes and that such change often results in conflicts between groups of fishermen. These conflicts occur between vessel size categories, gear types, vessels from different communities, or vessels from different countries, and often take a long time to settle into a stable agreement. Adding environmental changes in productivity and distribution of resources to this uneasy setting can clearly destabilize fishing agreements, formal or informal.

Similar to allocation agreements between groups of fishermen, many management measures designed to protect against overharvesting, habitat damage, or conflicts between fishing groups may be destabilized by changing environmental conditions (Miller et al. 2010). This is particularly so because the effects of climate change, are likely to be trends with a consistent direction (long-term increases or decreases in stock in a particular fishing area), though increases in variability of productivity may also be expected as natural resources adapt to changing conditions. In general, fishery management systems are designed around the assumption of stationarity in the underlying dynamics of the ecosystem, that is, these ecosystem properties have a constant mean and variance. Changing conditions that alter the average or variability of say productivity or species composition may mean the current management system will no longer be appropriate. For example, total allowable catches may need to be continually adjusted just to maintain exploitation rates constant through time if particular stocks decrease (increase) productivity. Allocation of the catch of various species between user groups may be fundamentally compromised by long-term changes in abundance and species composition. Reopening allocations or ongoing reductions in total allowable catches have enormous potential for disruption and conflict, since many contentious fishery management issues are about allocation between user groups in the first place. Similarly, the efficacy of closed areas or marine reserves may be affected by distributional shifts in species at different life stages. Again, the establishment of reserves in any fishery is often contentious because of the impacts on the allocation of fishing opportunities to different fishing groups. If changes in habitat, including temperature and other effects of climate change, mean that reserve areas must be renegotiated, then this is a major task for fisheries' managers and fishermen alike. The question of rates of change also arises: How long will a reserve be adequately sited if the location of spawning, feeding, or nursery grounds for various species are moving?

In the last two decades, there has been a shift toward the so-called 'rights based fishing' around the globe. That is, allocating fishing privileges or 'rights' with attendant responsibilities to adhere to conservation rules, to individual vessels, or groups of vessels, or communities. In this context, these rights include the full spectrum of systems from Individual Transferable Quota systems to Territorial Use Rights for an indigenous community (Beddington et al. 2007). But the systems have been constructed, as noted above, under the assumption that the natural system is stationary (constant mean and variance), which under climate change will likely no longer pertain. How will hard-won allocations to communities or businesses be altered by the effects of climate change on fishery resources? Distributional changes, productivity shifts, and ecosystem changes may make previously stable allocations highly unstable. Even if change is relatively slow, management systems will need time and information to adjust, given the difficulties of negotiating new arrangements for fisheries.

All of the above considerations apply for both national fisheries and those in international waters. Generally, high seas fisheries are governed by treaty organizations, as well as the provisions of the UN Law of the Sea. Regional fishery management organizations, composed of treaty member states that fish or have interests within a region, exist, for example, on both sides of the North Atlantic, in the Baltic, the Mediterranean, the Antarctic, the southeast Pacific, and for tuna fisheries in the central and western Pacific, the Indian Ocean, the Atlantic, and the eastern tropical Pacific. These organizations have been set up to manage fisheries with a focus on resource sustainability and allocation among member states. While they, like all fishery management, have a mixed record of success on sustainability of resources (Beddington et al. 2007; Garcia and Rosenberg 2010; Mora et al. 2009; Worm et al. 2009), they are the principal mechanism for limiting fisheries on the high seas. Illegal or unregulated fishing outside of national or international control is still a major issue (FAO 2001; Agnew et al. 2009), but will best be addressed by individual states and international organizations under treaty and Law of the Sea authorities (e.g., agreements on flag and port state responsibilities). These organizations will also need to deal with changing distribution and productivity of stocks under their jurisdiction (agreement between member states) with the added complication of having to negotiate between sovereign states. Virtually all such regional fishery agreements maintain the sovereign right of objection for members; they may act unilaterally if they cannot agree to management measures set by the organization. In other words, their participation and acceptance of management measures is voluntary and cannot be compelled by other states. This in effect slows the time it takes to make adjustments to changing conditions for fishery resources. The rate of change in fishing strategy, management effectiveness, and allocations between user groups is necessarily that of the member state that is willing and able to adjust most slowly. Similarly, controlling fishing opportunities in new areas or for newly productive resources to avoid overcapitalization and overharvesting will only occur with concurrence of all states capable of fishing within a region, unless preemptive action is taken to limit fishery expansions. Some international fishery management bodies have agreed to such preemptive action (e.g., in the Antarctic under the Commission for the Conservation of Antarctic Living Marine Resources), but it is not the norm. Climate effects on fisheries will make a precautionary approach to fishery management (FAO 1996) even more critical to avoid depletion of major fisheries.

In summary, the fisheries of the world will be vulnerable to long-term changes in climate biologically and from a policy perspective. While the actual time course of changes in fisheries resources is highly uncertain, it is quite certain that there will be major changes in productivity, distribution, and sustainable yield. This will affect the efficacy of management systems around the globe and the businesses, people, and communities that depend on fisheries for livelihood and food security. While there are clear needs to improve monitoring of fishery resources and fisheries to better understand the changes that are occurring, it is essential that a precautionary approach to management be implemented, as broadly as possible, in order for fisheries to continue to serve as a major source of food, employment and enjoyment globally.

2.08.1 Introduction

The primary impacts of climate on poultry production relate to resource competition (feed and water), disease and pest pressures, and a need to adapt to and manage the impacts of extreme and variable environments. These impacts are not unique to poultry production, but the reliance on current feed inventories, housing and ventilation systems, and adequacy of current biosecurity measures may translate to greater challenges for poultry and swine production systems, than for dairy and beef production systems that make use of open housing facilities and a wide variety of feeds and by-products that can be effectively digested by ruminant species. Challenges present opportunities for livestock production. Higher level of management offers the advantage of better control of input costs and ability to manage the impacts of extreme weather events as well as adapt to new and different market opportunities such as different feed ingredients or practices to reduce on-farm fossil fuel use. In a scenario in which a minimal contribution to climate occurs by livestock production (per unit of product) and is rewarded, the level of management and ability to adapt will determine those operations that will remain successful.

2.08.2 Contribution to Climate

On a global basis, FAO (2006) estimated that poultry production is responsible for 0.36 million tons of N_2O emissions per year as a result of applying poultry manure to croplands. Approximately 25% (or 0.09 million tons year^{-1}) originates from 'industrial agriculture' (see *Climate Vulnerabilities of the Swine Industry*, **Table 1**). Poultry production in North America occurs primarily in confined housing systems on large production units (see *Climate Vulnerabilities of the Swine Industry*, Table 1), contributing an estimated 0.04 million tons of N_2O year^{-1}, similar to that from swine and dairy production in North America. Estimates by the U.S. EPA (2011) indicate that 7.3% of US anthropogenic greenhouse gas (GHG) emissions, expressed as carbon dioxide equivalents (CO_2-eq), originate from agriculture. Enteric fermentation is the second largest source of CH_4 emissions, behind natural gas systems (U.S. EPA 2011). Burns et al. (2008) reported 5.24 Mg GHG emissions (CO_2-eq) monitored from broiler houses located in southeastern United States (per 1000 birds raised for 52 days). Their results indicated that CO_2 contributed to 88.6% of the total GHG emissions. Verge et al. (2009) for the year 2006, reported Canadian GHG emission inventories based on live weight (CO_2-eq) for broilers and culled layers at 1.0 kg hg^{-1}, turkeys at 1.44 kg hg^{-1}, and eggs at 1.73 kg per 12 eggs, respectively. Available literature indicates that poultry CH_4 emissions from enteric fermentation are negligible. Emissions of N_2O are the result of manure management land application of poultry manures.

Poultry manure management contributes a relatively small amount to global methane production from livestock systems (see *Climate Vulnerabilities of the Swine Industry*, **Table 2**; FAO 2006). Management of poultry manures in North America emitted approximately 0.16 million tons of CH_4 in 2004 (see *Climate Vulnerabilities of the Swine Industry*, Table 2). **Table 1** shows the CO_2-eq of US GHG emissions inventory from 2005 through 2009 from poultry manure management, whereas **Table 2** depicts the total GHG emissions from manure management (U.S. EPA 2011).

Wang and Huang (2005) estimated housing CH_4/N_2O emission based on life cycle analysis as from broiler chickens, Taiwan country chickens, and white Roman geese at 15.87/0.03, 84.8/16.4, and 1500/49 (mg per bird for life cycle), respectively. They calculated broiler enteric fermentation CH_4/N_2O emissions as 3.03/0.006, 14.73/2.84, and 9.5/0.31 (Mg year^{-1}), respectively, in Taiwan for the year 2000.

The AEA (2010) report estimated total CH_4 emissions from poultry operations in the United Kingdom as 12.64 Kt for the year 2008 and reported zero enteric CH_4 emissions. Although

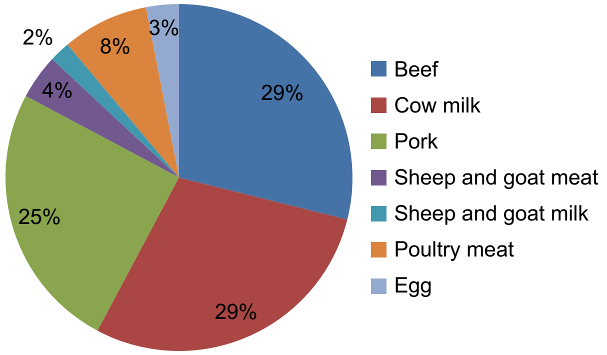

Figure 1 Total GHG fluxes of EU-27 livestock production in 2004, calculated with a cradle-to-gate life cycle analysis with common agricultural policy regional impact (CAPRI) model. Adapted from Leip, A., and Coauthors, 2010: *Evaluation of the LivestocKs Sector Contribution to the EU Greenhouse Gas Emissions – Final Report*, European Commission Joint Research Center. [Available online at http://www.fcrn.org.uk/research-library/meat/livestock/report-evaluation-livestock-sectors-contribution-eu-greenhouse-gas-emissions.] Accessed December 1, 2011.

this report estimated N_2O emissions from agricultural sector as a whole; however, this report did not estimate the N_2O emissions from poultry operations. Lesschen et al. (2011) reported GHG emissions for 27 European Union countries (EU-27) for poultry and egg at 1.6 CO_2-eq kg^{-1} and 1.3 CO_2-eq kg^{-1}, respectively. When summarized by livestock sector for EU-27, the poultry accounted for 6% of the total GHG emissions. Weidema et al. (2008) based on life cycle analysis (LCA) model assessed the impact of GHG emissions (CO_2-eq.) from EU-27. They reported 5–10% of the GHG emissions come from poultry sector and 3.6 kg CO_2-eq kg^{-1} by poultry weight basis. In a review paper, de Vries and de Boer (2010) from 16 European studies based on LCA method reported that production of 1 kg chicken resulted in 3.7–6.9 kg CO_2-eq, and production of 1 kg eggs resulted in 3.9–4.9 CO_2-eq. Figure 1 illustrates the livestock sector contribution of GHG emissions in EU-27 calculated based on the LCA method using the CAPRI model (Leip et al. 2010).

2.08.3 Vulnerabilities

Poultry flocks are particularly vulnerable to climate because birds can only tolerate narrow temperature ranges. Higher temperatures increase risks of heat stress in flocks and can result in reduced egg production and growth rates. IPCC predictions depict increases in mean annual temperature by as much as 2 °C over the next century (Meehl et al. 2007). The challenges posed by increased temperature may be either decreasing productivity or increasing cost. Although confined systems have the advantage of being able to control the indoor environment, it is at an economic and energy cost. To maintain productivity, housing systems need to be managed to maintain optimal temperatures, and increased investment will be required in ventilation and cooling to counteract higher temperatures. Often water is used to provide cooling. But as discussed, water resource concerns may limit the expansion of this practice and may even require that alternatives be found. Increased use of fossil fuels to provide cooling is not desirable when in a situation in which the objective is to reduce the carbon or environmental footprint of the farm. This leaves use of renewable energy or bioenergy sources to provide cooling. To maximize 'free cooling' building designs and design of ventilation systems may require reconsideration. Stocking density may need to be reduced in extreme temperatures, potentially increasing costs. The depressive effect of heat stress may increase the rate at which poultry bird consumes water and consequently reduce the egg shell thickness (Kekeocha 1985). Also, it has been reported that preconditioning broilers to heat stress to encourage better survival during transport could lead to more variable breast meat pH and affect meat quality (Gregory 2010). Furthermore, extreme weather events, such as storms, would increase stress and may adversely affect productivity, and cause higher mortality, especially for outdoor flocks.

In addition to engineering solutions that provide an adaptation mechanism for climate, there is a longer term need to consider animal genetics and opportunities with genetics to develop an animal that is productive while more resilient to temperature extremes, particularly heat stress. Current breeds that are heat tolerant tend to have lower productivity. To meet the food needs of a growing human population that, globally, desires more animal protein, heat tolerant breeds that do not compromise performance need to be developed.

Plausible future climatic conditions suggest that in some parts of the world extended drought periods would further challenge water supplies and competition between water use for households and drinking water versus water use for agriculture production. In other parts of the world, annual precipitation may increase, but this may be accomplished through increased frequency of extreme events. Animal housing infrastructure and maintenance may have to cope with more intense weather events and increased rainfall. This also has implications for sizing manure storage structures. In many areas the amount of rain projected from a 25-year, 24-h storm event could increase, thereby increasing the size of manure storage needed to accommodate that rainfall that directly deposits into the manure storage as well as that collected from the production area if roof runoff is not redirected away from lots. For most poultry operations, birds are raised in confinement, precluding the need to collect roof runoff. In litter and stack systems, typical of most poultry production facilities, litter remains in the house or under the roof until land applied; thus, the manure storage issues associated with increased precipitation resulting from a 25-year, 24-h storm event can be avoided. However, this challenge remains for most swine, dairy, and beef operations.

2.08.4 Resource Competition

Some of the indirect effects of climate are through feed resources, the buffering abilities of ecosystems, increased desertification processes, increased scarcity of water resources, lower production of grain, and so on (Thornton et al. 2007). There are also challenges related to the potential shortage of feed owing to a rapid increase in production competition among food, feed, fuel, and land use systems. With increasing production of biofuel crops on finite land resources, the price of corn is presently priced at an all-time high. In spite of constant improvements in yield, increased arable acres devoted to biofuel crop production coupled with increasing demand on grain as a food crop for a growing population creates competition among bioenergy, food, and feed demands. This leaves livestock production in a vulnerable position if it is to remain profitable. Ruminant species can take advantage of forage crops unsuitable for human consumption; leaving competition for forage crops to be had between bioenergy and feed purposes. Nonruminant species, such as swine and poultry, cannot digest high-fiber forage feeds and therefore rely heavily on grain crops. Climate affects swine and poultry industries indirectly by its impact on the availability and price of crops used for animal feed. More pressure will be put on the swine and poultry industries if the extensive grains industry is affected. If cropping regions are shifted, the swine and poultry industries, which are mostly located in current cropping regions, will have to be relocated accordingly or deal with increased transport cost of feed.

Co-products and by-product feeds offer promise as energy and protein sources for the livestock industries. Some by-products, such as distillers dried grains with solubles that result from grain-derived ethanol production, have been thoroughly investigated a feed for laying hens, broiler chickens, and turkeys. At present, recommended diet inclusion levels are at no more than 20% of the diet, replacing corn and some soybean meal (Applegate et al. 2009; Wang et al. 2008; Ferket and Gernat 2008). Other by-product and co-product feeds need similar assessment before these alternative feeds can effectively be adopted by the industry. However, access to feeds and affordability of feeds will drive the need to conduct the necessary research that provides recommendations for inclusion of nontraditional feedstuffs. Regardless, it is unlikely co-products and by-products can completely replace primary grains in poultry diets, leaving some competition inevitable.

One of the trade-offs of using co-product or by-product feeds is that nutrients are more concentrated than in the original grain. This includes a concentration of nitrogen, phosphorus, and fiber. Often, these feeds are included in diet formulation as a protein source and the overall diet is not different in protein content between the formulation with the grain and the formulation with the by-product or co-product. Phosphorus content, however, can be considerably greater in the diet containing the co-product or by-product feeds resulting in greater phosphorus excretion in manure unless removal of supplemental dietary phosphorus can offset the contribution from the co-products or by-products. Excessive manure phosphorus has surface water quality implications if not managed properly. Dietary fiber increases as a result of dietary inclusion of co-product or by-product feeds. This increases fiber content of manure and manure mass and volume excreted (Applegate et al. 2009), necessitating greater storage area for manure. Because the amount of storage area needed for manure is increased, the overall footprint of the farm may increase (surface area) and the surface area of the manure storage likely increases, providing the potential for more emissions to result because of the increased size of emitting surface.

Water resources, like land, are finite and we already see competition for water. Meat birds (broiler chickens and turkeys) grown in litter-based housing systems use minimal water. Drinking water is the primary use and far surpasses quantities used for other purposes, on farm. Laying hen facilities with egg processing onsite use water for cleaning eggs (3300 m^3 per ton of eggs) (Mekonnen and Hoekstra 2010). In addition, some poultry facilities use water as part of a cooling strategy. With increasing mean temperatures and increasing frequency of extreme events, including heat waves, the need for cooling in confined systems is expected to increase. Animal agriculture may come under scrutiny for its water consumption. Although poultry production uses less water than other livestock systems (i.e., dairy and swine) it is not immune to the effects of water shortfalls or consumer demand to reduce the water footprint of food production.

2.08.5 Diseases and Pests

Increasingly in crop production new pests are being found in areas in which they were previously absent. Examples include the brown marmorated stink bug and spotted wing *Drosophila*. Alpine forests in Canada have fallen prey to pests that previously were excluded because of a shorter growing season. Pest prevalence is changing, and this change has been attributed to increasing mean temperatures, milder winters, and longer growing seasons (Patterson et al. 1999). Increasing temperatures evaporate more water into the air and cause a proportional rise in humidity that provides a medium for fungal and bacterial growth. There are chances of increased persistence of some endo- and ectoparasites and increased mycotoxins in feed associated with increasing temperatures. Disease prevalence and strains of diseases, including viruses and pathogens, may have long-term implications for poultry production. Bronchitis is among the few that are transmitted via moist air breathed by the birds. At risk are animal productivity and the potential for transfer of disease to humans.

Complicating the situation is increased societal pressure to minimize or eliminate preventative or nontherapeutic administration of antibiotics in feed and water. Although routine vaccination is common practice in modern livestock production, vaccination protocols are uncommon in meat bird production because of the short lifespan of the animals (42–49 days for broiler chickens, 16–22 weeks for turkeys), and consumers express concern over resistance to common vaccines. Adaptation to increasing disease challenges might require more advanced biosecurity protocols or a change in housing practices to facilitate better interruption of disease cycles. Practices could include reduced animal density within animal housing, potentially increasing the footprint of a farm and increasing the product cost to the consumer.

2.08.6 Mitigation Opportunities

On-farm energy generation is one opportunity to mitigate the contributions of livestock production to climate. The impacts of on-farm energy generation through the use of anaerobic digesters are discussed in greater detail elsewhere in this book. Although anaerobic digestion is considered an option for liquid manures, for drier manures such as those generated in poultry production the potential is more limited owing to mixing and flow challenges. A more promising alternative is gasification. Not widely adopted in agriculture systems, use of gasification is on the rise, particularly in Europe and installations are underway in the United States. The economics and potential to offset fossil fuel use needs further evaluation at commercial scale.

Poultry are the most efficient converters of feed to food product of all livestock species. Further improvements in feed efficiency through animal genetics can further reduce manure production mass, thereby offsetting the challenge of needing greater manure storage as a result of feeding co-product or by-product feeds. Improvement in feed conversion efficiency has the added benefit of decreasing the pressure to access and afford grain as a staple ingredient in the poultry diet.

Poultry housing systems are presently designed to minimize water contamination by manures throughout the manure storage phase. Capture and treatment of gases exhausted from buildings (NH_3) offers an opportunity to reduce contributions to N_r. Opportunities exist to minimize N_2O losses when manures are stored in the field before land application and following land application of manures. Managing timing of land application, optimizing soil moisture content at time of manure application, and minimizing time that litter sits in a field uncovered are all opportunities to reduce the environmental impact of poultry production.

2.08.7 Conclusion

Global food demands must be balanced with reduced environmental impact of food production. As the growing global populations seeks to incorporate more animal protein in the diet, the production of animal protein must be met while addressing challenges posed by climate. The challenges include direct effects of climate on the animal, as well as indirect effects through feed supply or disease susceptibility that are affected by climate. This will require that the poultry industry think creatively about how to produce meat and eggs in a manner that is profitable and less reliant on traditional feed resources, fresh water supplies, and fossil fuels.

2.09.1 Introduction

When considering how swine production is affected by climate, perhaps the best place to start is to consider the present day vulnerabilities of the industry. The swine industry, like most of the meat production industry, is based on intensive production (Aneja et al. 2009) with trends suggesting future increases in intensification. This industry model depends on cheap grain, cheap energy, and manageable disease control. Zhao et al. (2005) opined that plausible changes in temperature, and precipitation frequency and intensity may have direct impacts on nonintensive swine production, but is not likely to directly affect intensive production because the barn environment is controlled. However, an increase in the frequency of both severe storms' (e.g., hurricanes, tornadoes, etc.) intensity and severity is also plausible. Increased storm intensity might be expected to increase the likelihood of upset of large open-air lagoon treatment systems, and increased severity has the potential to inundate the barns (Aneja et al. 2001). This could lead to increased pressure on intensive operations to modify current manure treatment systems. Climate could have negative impacts on feed grain production which would affect its availability and price. Climate influences will also have indirect impacts on energy costs as demands for renewable energy increase which could also put upward pressure on feed grain prices as bioenergy production competes for feed grains. The climate impacts on growth, reproductive success, and distribution of diseases may impact the ability to manage disease. This concern may be heightened in intensive production relative to nonintensive systems due to the density of animals. Future greenhouse gas (GHG) mitigation efforts may produce costs or revenue opportunities for the swine industry. Last, the role of reactive nitrogen (Nr) in climate and other intertwined issues could be very important. Swine producers will need to adapt to all these effects to maintain production levels.

2.09.2 GHG Emissions

US Environmental Protection Agency (US EPA) listed methane (CH_4) and nitrous oxide (N_2O) emissions from manure management among its 19 key categories which exert significant influence over the US total inventory. (CAST 2011). GHG losses from swine production occur in the barn, during treatment and storage of manure, and during and after land application of manure. US swine manure management systems are relatively high in GHG emissions because most swine manures are stored wet rather than dry (CAST 2011). Direct emissions of GHG from animal production in the United States have been estimated to be 203 Mt CO_2 Eq (carbon dioxide equivalents), or about 2.9% of the total US emissions (6957 Mt CO_2 Eq) in 2008 (CAST 2011). Swine production in Canada has been estimated to be 1835 kt CO_2 Eq or about 0.3% of total Canadian emissions (CAST 2011). The majority of the Canadian GHG emission estimate is derived from CO_2 from respiration (with 37.5% of CO_2 coming from manure degradation in the pig house) (CAST 2011).

Disparity between these livestock industry-related GHG contribution estimates and the 18% of total GHG contribution estimated by the FAO (2006) is caused by the inclusion in the UN FAO calculations of land use changes to produce feed grain and pasture for livestock. Whether or not deforestation to establish feed crop fields (or new pasture) should be included in the livestock industry's GHG emissions' estimate has been debated. For example, the recent CAST report (2011) points out that deforestation is not happening in the United States and therefore GHG emissions from deforestation should not be considered as part of the US livestock industries carbon footprint.

2.09.2.1 Nitrous Oxide Emissions

Estimates of N_2O emissions from swine barns in the United States range from 0.8 to 21 g N_2O day^{-1} AU^{-1} (AU = animal unit = the number of animals equaling 500 kg) (Cast 2011).

http://dx.doi.org/10.1016/B978-0-12-384703-4.00217-3

Estimates for N_2O losses from swine manure anaerobic lagoons in North America have been estimated at 20 g N_2O $year^{-1}$ $animal^{-1}$ (Cast 2011). Estimates of losses from anaerobic lagoons in North Carolina (USA) were reported as 0.3–0.4 kg N_2O day^{-1} ha^{-1} (Harper et al. 2004). (If one assumes the average anaerobic lagoon surface area of a 4000 head feeder to finish farm in North Carolina is approximately 3 acres (or 1.2 ha; Zehring et al. 2005), the Harper et al. (2004) estimate of N_2O emissions equals approximately 38 g N_2O $year^{-1}$ $animal^{-1}$.) Swine manure composted in deep bedded straw has been estimated to emit 58.9 g N_2O ton^{-1} of compost (CAST 2011).

Land application of liquid swine manure has been estimated by Harper et al. (2004) to emit 2.6–3.8 mg N_2O day^{-1} m^{-2} (versus 0.0016 mg N_2O day^{-1} m^{-2} before application). A yearly N_2O flux from land application of hog manure has been estimated at 61.3 mg N_2O m^{-2} (CAST 2011). (The Harper et al. (2004) daily estimate would equal the annual flux reported by CAST (2011) in less than 20 days.)

On a global basis, FAO (2006) estimated that swine production is responsible for 0.44 million tons of N_2O emissions per year with 25% (or 0.11 million tons $year^{-1}$) coming from industrial agriculture (**Table 1**). Swine production in North America, which is primarily intensified production (or industrial as labeled in **Table 1**), was estimated at 0.04 million tons of N_2O $year^{-1}$. Nitrous oxide emissions estimates in China and Western Europe are approximately 5 and 2 times higher, respectively, than that estimated for North America.

2.09.2.2 Methane Emissions

Methane emissions from swine barns have been estimated at 48–54 g CH_4 day^{-1} AU^{-1} (CAST 2011), and up to 160 g day^{-1} AU^{-1} for deep pit and pull plug finishing barns (CAST 2011). Estimates of lagoons emissions of CH_4 have varied widely from 0 to 188 g CH_4 day^{-1} AU^{-1} (CAST 2011). Measurements of average CH_4 emissions have been reported as 154 g CH_4 day^{-1} AU^{-1} (CAST 2011) and 21.4 g CH4 day^{-1} AU^{-1} (CAST 2011). Swine manure composted in deep bedded straw has been estimated to emit 254 g CH_4 ton^{-1} of compost (CAST 2011). Methane emissions from land application of liquid swine manure vary by time of application and method of application. Fall applications of swine manure have been estimated to emit twice as much CH_4 as springtime application (5.5 kg CH_4 ha^{-1}, 2.35 kg CH_4 ha^{-1}, respectively (CAST 2011)) with 98% of the emissions occurring in first 4 days.

Manure management in the United States emitted approximately 1.9 million tons of CH_4 in 2004 (**Table 2**). Swine manure management contributes the largest share of methane emissions relative to poultry and other livestock – almost half of which are from industrial swine production. Globally, nearly one-fourth of total CH_4 emissions are from industrial hog production (FAO 2006).

2.09.2.3 Carbon Dioxide Emissions

Global fertilizer production for feedcrops is estimated to be responsible for annual emissions of more than 40 million tons of CO_2 (**Table 3**). The emissions from fertilizer production for feed grains in the United States is about 29% of the total (11.7 million tons of CO_2), second only to China (14.3 million tons of CO_2).

CO_2 emissions induced by on-farm fossil fuels use for feed production may be 50% higher than that from feed-dedicated N fertilizer production; that is, 60 million tons of CO_2 globally (FAO 2006). Carbon dioxide emissions from on-farm energy use in Minnesota for swine are estimated at approximately 0.6 million tons $year^{-1}$ (**Table 4**). If this rate is used to estimate the

Adapted from FAO, 2006: *Livestock's Long Shadow: Environmental Issues and Options*. Food and Agricultural Orgainzation fo the United Nations, Rome, Italy. ISBN 978-92-5-105571.

CO_2 emissions by on-farm fossil fuel use for the US swine population of 65 million head in 2011 (USDA 2011), the overall CO_2 emission would be approximately 8 million tons year^{-1}.

2.09.3 Disease

Increased temperatures, more acidic conditions, and higher salinities for freshwater ecosystems have resulted in lower avian influenza survival in lab experiments (Vandegrift et al. 2010). Although these conditions suggest decreased survival of influenza viruses in the environment, predicting net impacts of climate conditions requires consideration of how viruses interact with other factors such as smaller, shallower wetlands, increased crowding, stress, and contact rates among migratory species and between wild and domestic birds and transmission to the swine population.

Some have predicted that the affects of disease under plausible future climate would be more pronounced in developing countries in humid and subhumid tropical climates (Zhao et al., 2005). However, the most recent episode of a novel H1N1 virus, which was widely reported to have first appeared on a swine farm in Mexico, a tropical developing country, quickly spread across the globe. Swine are recognized as mixing vessels in which swine, avian, and human influenza strains mix and match. Concerns have been expressed that widespread use of influenza vaccinations in intensive swine production may be 'pressuring change' in influenza evolution, helping to select for unique variants (Wuethrich 2003). Although the positive benefits of vaccinations are felt to outweigh the immunological pressure on influenza, if there are changes in enhanced influenza distribution in response to alterations in local and regional climate, the role the swine population plays in influenza evolutionary biology could become increasingly problematic.

2.09.4 Reactive Nitrogen Loss during Swine Production and Waste Management

Emissions of Nr have a complex effect on climate by altering global radiative forcing (Butterbach-Bahl et al. 2011). They directly affect the GHG balance through N_2O emissions and indirectly affect it by increasing tropospheric O_3 levels, altering methane fluxes and biospheric CO_2 sinks (including Nr deposition and O_3 effects) (Figure 1). Conversely, aerosol formed from NO_x and NH_3 emission (not shown in Figure 1) also has a cooling effect.

Modern agriculture uses large quantities of inorganic commercial N fertilizer to enhance crop productivity, currently supporting the production of about half the food consumed by the human population (Erisman et al. 2008). However, the flip side of the coin is that high levels of Nr are being released into the environment, causing numerous undesirable symptoms (e.g., algal blooms, hypoxic zones, eutrophication, ground water contamination, acid rain, atmospheric N deposition, overfertilization of terrestrial areas, increased tropospheric ozone, decreased stratospheric ozone, fine particulate matter, increased GHG) (US EPA 2011). As a result of the high mobility of Nr, agriculture is a leaky system when it comes to Nr. Much of the Nr released to the environment is from commercial inorganic N (Figure 2).

An Nr flow model for a Danish swine farm shows an example of quantities of the nitrogen introduced to the swine farm as feed, fertilizer, seed, and atmospheric deposition and its distribution into animal and crop products and losses as gases (NH_3, N_2, N_2O), and in soluble forms (DON, NO_3) (Figure 3). NH_3 emissions vary by housing type; animal size, age, and type; manure management, storage, and treatment; and weather variables, and can be expected to be higher in liquid-based systems which are more common in the United States than in Denmark. In their review, CAST (2011) reported that across a multistate (US) set of measurements and life cycle aspects, average NH_3 emissions were 48 and 30 g day^{-1} AU^{-1} for gestating and farrowing sows. Average NH_3 emissions for finishing barns ranged from 102 to 130 g day^{-1} AU^{-1} in deep-pit systems and 77–81 g day^{-1} AU^{-1} from pull plug barns. Specially formulated diets (low protein with synthetic amino acids) have been found to reduce NH_3 emissions by almost half.

Open air storage and treatment of hog manure in earthen anaerobic lagoons, typical in the southern and southeastern United States, can emit 5–40 g NH_3 day^{-1} m^{-2} (CAST 2011). Concrete storage pits are more common for swine manure in the Midwest United States with ammonia emission rates typically around 5–50 g NH_3 day^{-1} m^{-2}. (It should be noted that anaerobic lagoons have a much larger footprint than concrete storage pits.) Land application of liquid manure from a lagoon can result in large losses of NH_3 with levels greater than 100 g NH_3 day^{-1} m^{-2}. Manure land application using deep or shallow injection and drag shoe methods can decrease ammonia loss from 90+, 80+, and 60+%, respectively.

The first assessment of the overall effect of Nr emissions (between 1750 and 2005) on radiative forcing was conducted in Europe (Figure 4) (Butterback-Bahl et al. 2011). The main warming effects are from N_2O emissions (average of 17 mW m^{-2} with a range from 15 to 19 mW m^{-2}) and from reduction in the biospheric CO_2 sink by tropospheric O_3 effects on plants (average of 4.4 mW m^{-2} with a range of 2.3–6.6 mW m^{-2}). The main cooling effects are estimated to be from increasing the biospheric CO_2 sink through fertilization effects of atmospheric Nr deposition on N limited ecosystems (average (−)19 mW m^{-2} with a range of (−)30 to (−)8 mW m^{-2}) and by light scattering effects of Nr containing aerosols (average (−)16.5 with a range of (−)27.5 to (−)5.5 mW m^{-2}). Overall, European Nr emissions are estimated to have a net cooling effect, with uncertainty bounds ranging from substantial cooling to a small net warming (average (−)15.7 with a range of (−)46.7 to (+)15.4 mW m^{-2}).

The largest uncertainties concern the aerosols and Nr fertilization effects. In addition, published estimates suggest that the default N_2O emission factor of 1% used by the IPCC for indirect emissions from soil following Nr deposition is too low. Davidson (2009) estimated that 2–5% of manure and fertilizer Nr was emitted as N_2O as a result of microbial activities subsequent to land application. Crutzen et al. (2008) estimated 3–5% of newly produced Nr was emitted as N_2O.

Bleeker, P. Grenfelt, H. van Grinsven, and B. Grizzetti, Eds., Cambridge University Press.

Livestock production and manure management exert various influences on the environment and make up a relatively large share of the total emission of N_2O. Most effects deal with land use changes and nutrient element cycling. These have increased over the last decades particularly in response to the trends in livestock production to scale up in size, intensification, specialization, and conglomeration in regional clusters. These trends are facilitated by the availability of cheap energy, transport infrastructure, and cheap Nr fertilizer for boosting the production of animal feeds (Erisman et al. 2011).

Though livestock production consumes less than 3% of the global net primary productivity, its contributions to the global burden of NH_3, CH_4, and N_2O to the atmosphere range from 10 to 40% (Butterbach-Bahl et al. 2011). In addition, globally livestock excrete about 100 Tg Nr year^{-1}, but only 20–40% of this amount is recovered and applied to crops. The rest is lost to the environment, wherein it moves among soil, water, and air media in a process known as the nitrogen cascade, resulting in undesirable public health risks and environmental damage (Galloway et al. 2003; US EPA 2011).

Industrial production of Nr may be considered as having increased along with livestock and human populations (Butterbach-Bahl et al. 2011; Erisman et al. 2008). Expected substantial net warming effects of these wider Nr interactions remain to be quantified. Although individual components of the Nr emissions have cooling effects, there are many opportunities for 'smart management' linking N and C cycles (Butterbach-Bahl et al. 2011). These can help mitigate GHG emissions while reducing the other Nr related threats. Efforts need to focus on reducing the warming effects, while recognizing that the adverse effects of particulate matter and nitrogen deposition on human health and biodiversity may more than outweigh their climate benefits. (Sutton et al. 2011).

2.09.4.1 Estimates of Damages from Nr Emissions

Estimates of the monetary damage resulting from efforts to manage Nr losses have been calculated for Europe. Although these estimates consider impacts outside those associated with climate, these costs will likely add to, and be comingled with, the climate mitigation pressures experienced by swine and

Figure 3 Annual nitrogen flows (kgN ha^{-1}) in a typical Danish swine farm. This example assumes no manure export. Jarvis, S., N. Hutchings, F. Brentrup, J. E. Olesen, K. ven de Hoek, 2011. Nitrogen flows in farming systems across Europe. *The European Nitrogen Assessment*, M. A. Sutton, C. M. Howard, J. W. Erisman, G. Billen, A. Bleeker, P. Grenfelt, H. van Grinsven, and B. Grizzetti, Eds., Cambridge University Press.

other meat producers. European limits are already in place for land application of N in manure (170 kg ha^{-1}) for arable lands in Europe (Brink et al. 2011). These limits have increased costs for the pig and poultry sector by €10 ton^{-1}, amounting to a national cost of €90 million in 2006. About half of these costs are related to additional costs for remunerations to farmers for accepting the manure (transfer costs are not considered for national assessments) (Brink et al. 2011).

Estimates of the total annual damage in the 27 countries in the EU as a result of emissions of N_2O, NO_x, and NH_3 to air and water in 2000 from all sources, ranged from €70 to 320 billion. This corresponds to a welfare loss of €150–750 per capita, which is equivalent to 0.8–3.9% of the average disposable per capital income in 2000. About 60% of the damage costs are related to human health, 35% to ecosystem health, and 5% to the effect on GHG balance (Figure 5).

Figure 5 and Table 5 show that the unit damage costs for N_2O are small compared with other costs items, implying that N policies for agriculture should not focus on reduction of emission of N_2O alone. However, when part of the N addition is in the form of manure, the difference between externalities and net crop benefits will increase in view of the higher emission factors for ammonia (up to 70%) and the lower fertilizing efficiency of N in manure as compared with chemical fertilizer. In view of the high unit damage cost for ammonia, the use of manure without applying far-reaching low emission

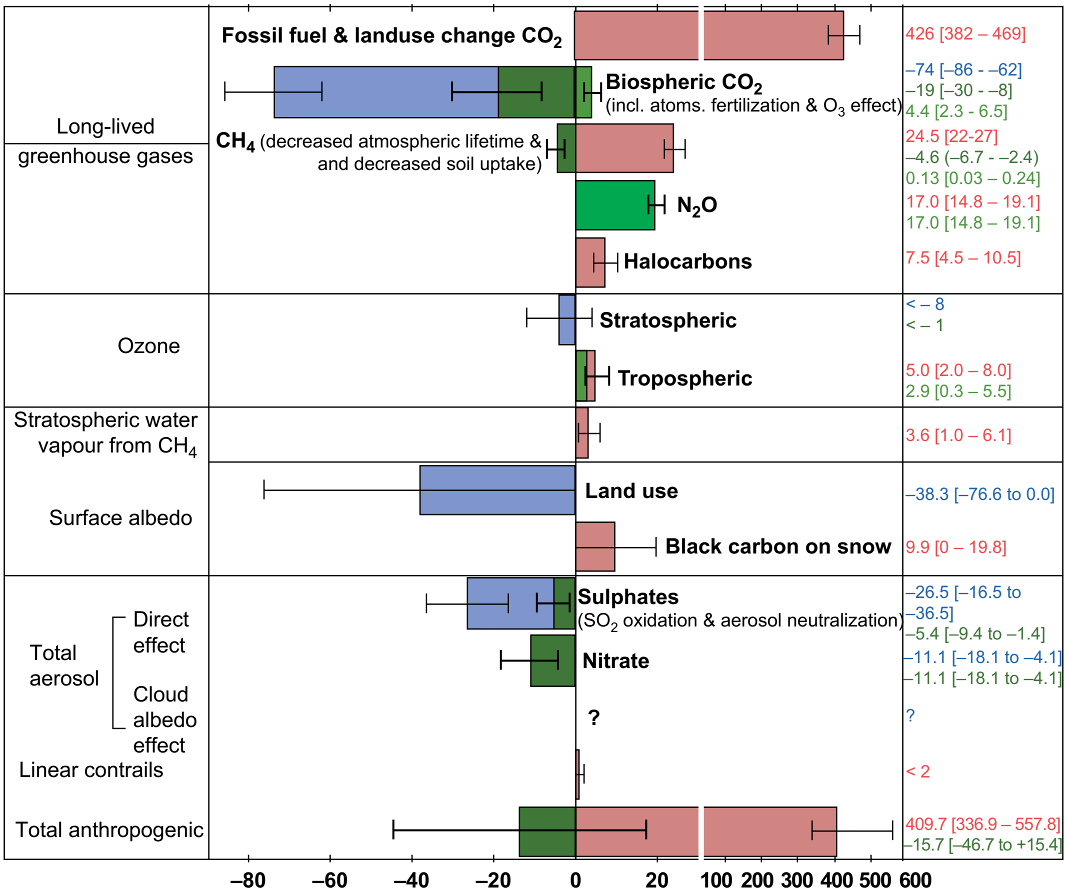

Figure 4 European contribution to global radiative forcing (mW m^{-2}). Butterbach-Bahl, K., and Coauthors, 2011: Nitrogen as a threat to the European greenhouse balance: *The European Nitrogen Assessment*, M. A. Sutton, C. M. Howard, J. W. Erisman, G. Billen, A. Bleeker, P. Grenfelt, H. van Grinsven, and B. Grizzetti, Eds., Cambridge University Press.

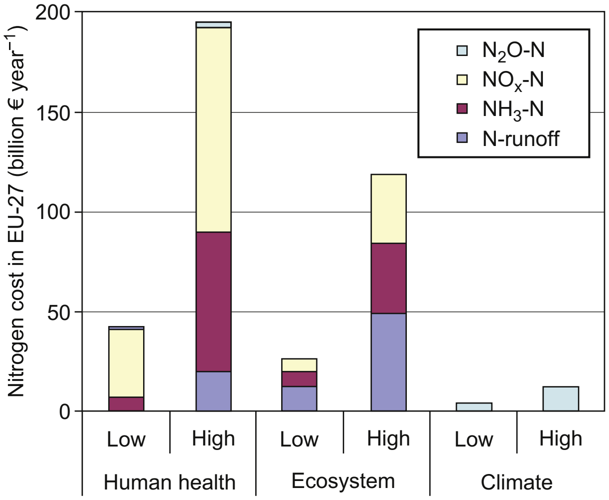

Figure 5 Low and high estimates of the total social damage in EU 27 as a result of environmental N-emissions in 2000. Grenfelt, H. van Grinsven, and B. Grizzetti, Eds., Cambridge University Press.

techniques therefore would often be not beneficial for society. Stricter regulation of manure application and improved N efficiency would provide robust benefits for society.

Annual marginal social costs of N damages are between 20 and €150 billion, as compared with annual benefits of N fertilizer for farmers between €10 and 50 billion or €20 and 80 billion when including long-term benefits of secure soil N availability (Brink et al. 2011). These results suggest that at the present level of N fertilization, the marginal environmental costs tend to be close to the marginal agricultural benefit. As Nr emissions and social impacts increase proportionally with the use of N fertilizer, and effects on crop yield levels off, the risk of externalities exceeding crop benefits will tend to increase with higher inputs. However, it should be stressed that the upper bounds of the environmental costs are theoretical and have lower probability of occurrence than the empirically based upper bounds of the agronomic benefits.

So whether the drive to reduce Nr losses from swine production is propelled by climate concerns, public health risks, environmental damage, or some combination of all of these, pressure on swine producers to better manage Nr and prevent loss to air, water, and soil will increase. The intertwined trends in GHG emissions, population growth, and concern

over public health and environmental risks are difficult to unravel (Table 6). However, opportunities to receive compensation for reduction in Nr losses might be best achieved by GHG emission reduction by way of offset credits. Thus elucidation of the role of Nr emissions in climate might be of benefit to the industry.

2.09.5 Diet Implications

If the impacts of climate become more apparent, the call for action among the common citizen, their elected representatives and regulatory agencies will likely get more urgent. This scenario presents a further risk to swine production as the full suite of climate impacts related to dietary choices would likely also come under scrutiny. As detailed above, not only are the direct emissions of CH_4 and N_2O from meat production and manure management involved in the accumulation of GHG, but the indirect role of Nr in climate and other undesirable effects on public health and environment are also of concern. The amount of Nr lost to the environment during the production of protein in milk, egg, and poultry is much less than in pork and especially beef, indicating a shift from beef to pork to poultry, and milk would also decrease the Nr use (Tables 7–9).

In a recent review by Winiwarter et al. (2011), several studies of human diet were discussed. In one study, three meal options with similar energy and protein contents were evaluated. GHG emissions varied from 0.42 (soybean) through 1.3 (pork) to 4.7 (beef) kg CO_2 eq. Another study compared four diets and included a 'healthy diet' based on sparing consumption of meat (daily intake of 10 g beef, 10 g pork, 46.6 g chicken meat and eggs, and 23.5 g fish per capita) (Table 10). Using annual meat production and shares of domestic production, the average intake of meat products and eggs per capita in the EU was compared with consumption in the case of the healthy diet. The reduction in consumption of pork relative to the healthy diet is highest at 87%. The total potential reduction in meat and egg consumption is 63%. As the milk demand is kept stable, there is no reduction in the number of dairy cattle. The number of cattle, pigs, and poultry can be reduced because of the decreased demand for their products. Simple calculations show that N excretion in the EU could decrease by about 44% and the ammonia emission by about 48%. The potential decrease in ammonia emissions is somewhat higher because the number of housed animals (which contribute more strongly to NH_3 emissions) decreases whereas the number of grazed animals remains constant. In essence, low meat diets may result in lower GHG emission and lower ammonia emissions (Table 10). Efforts to lower the Nr loss

Table 6 Quantifiable targets to avoid deterioration due to nitrogen

Environmental problem	*Nitrogen connection*	*Target*
Loss of ecosystems services due to: • Acidification • Eutrophication • Biodiversity loss	Atmospheric deposition of nitrate and/or ammonia	Critical loads (exceedance of soil specific values)
Adverse impact on plant species composition	Atmospheric concentration of ammonia	Critical levels (exceedance of critical NH_3 concentrations)
Crop damage	O_3 formation (NO_x chemistry)	Accumulated exposure over threshold
Human health	NO_x concentration	Years of life lost
	O_3 formation (NO_x chemistry)	Disablement Adjusted Life Years
	PM formation (NO_x chemistry and ammonia)	Quality standard (concentrations)
	Nitrates in drinking water	
Climate change	N_2O emissions CO_2 emissions/uptake, as the natural C cycle is influenced by N in the environment O_3 formation (NO_x chemistry)	Global mean temperature (limit: 2 °C increase above preindustrial)

from swine operations could help reduce the GHG impacts of diets containing pork products.

2.09.6 Mitigation Opportunities

Given the array of undesirable impacts of swine production associate with GHG and Nr emissions, the industry would be well served to diligently explore opportunities to reduce such emissions. Perhaps one of the most straightforward mitigation opportunities lies in the capture of CH_4 emissions from manure storage/treatment systems using anaerobic digesters. The best use of the CH_4 captured by anaerobic digesters is renewable energy production, either electrical, heat, or both (i.e., cogeneration). In addition to energy, GHG offset credits could potentially also be sold on the voluntary or regulatory market. Even if the CH_4 is flared, given that CH_4 has a global warming potential (GWP) of 21 (IPCC 2007), the CO_2 emitted (with a GWP of 1) results in much lower radiative forcing. Currently the economics of anaerobic digestion are challenging. Registration and verification processes for GHG credit sales add additional hurdles. In addition, management of anaerobic digester effluent is also needed to prevent loss of NH_3. However, NH_3 emission controls also offer the potential for additional revenue from N water pollution offset credits or capture for sale as fertilizer (Rudek and Aneja 2011). Given the benefits to society of reducing commercial fertilizer use (e.g., less energy use, less Nr emissions) by recycling NH_3 captured from manure into a concentrated product that can be efficiently transported, a cogent argument can be made that incentive payments along the lines of those provided for biodiesel production would be in society's interest.

More widespread and efficient use of the Nr in manure is also needed to reduce undesirable impacts. Long-term changes could include a shift of the industry to areas that can use additional manure for crop fertilization. Once NH_3 losses are controlled, much more Nr will need to be managed. Many swine operations will not have the addition farm land or crop needs to absorb the additional Nr. Options for managing the additional Nr include denitrification, NH_3 capture and concentration, or production of a manure value-added product (e.g., compost, vermicompost). Care will need to be taken that denitrification treatment systems are optimized to avoid high levels of N_2O byproducts. With GWP of about 310 (IPCC 2007), even small percentages of N_2O can quickly add up to large increases in radiative forcing.

The swine industry has been effective in increasing the feed conversion efficiency, providing financial benefits in reduced feed costs, which could become increasingly important if feed grain prices increase. Modifications in swine diets could also help in reducing Nr concentrations in manure and hence Nr losses.

Adapting to possible increased precipitation and more severe storms translates into reducing the risk of upset of treatment systems and barn flooding. Excluding rainfall from manure treatment systems and moving barns and manure treatment systems out of flood plains seem the most reasonable modifications to minimize threats from precipitation pattern changes. Again anaerobic digesters may be the most prudent treatment system to adopt to exclude rainfall.

The potential for intensive swine production to become a source of novel influenza viruses as a result of alterations in climate patterns and increased density of swine production suggests that it would be prudent for both the swine industry and the society to increase its surveillance of novel influenza strains appearing in the swine herd.

2.09.7 Conclusion

Modern agriculture provides food for an increasing number of humans through intensive agriculture. To achieve this feat, agriculture has gone through major changes over the last few decades becoming increasingly intensified. Massive use of industrial fertilizers has improved crop yields, and efficient concentrated animal feeding operations (CAFOs) dominate the production of swine both in the United States and abroad. However, on a global basis, agriculture is now recognized as a major force pushing the environment beyond its 'planetary boundaries' (Rockstrom et al. 2009). Clearly something must be done to reform agriculture and particularly livestock production, to reduce its contributions to air, water, and soil pollution, and increasingly human health and climate concerns.

Wendell Barry is famously quoted as saying, "The genius of American farm experts is very well demonstrated here: they can take a solution and divide it neatly into two problems" (Barry 1996). If reduced meat consumption, often cited as one of the solutions from reducing agriculture's negative environmental impacts (see for example Foley et al. 2011), is not to be the only solution to reducing environmental impacts, modern livestock producers must show that its genius can be applied to greatly reducing the massive footprint of livestock agriculture. As Barry implies, capturing the resources inherent in manure must be part of the solution.

Agriculture (both animal and crop) do not have to be a source of human health, climate, air, water, and soil quality problems; they can and should be a source of solutions. Society must invest in the research needed to find solutions. However, it is also critical that farmers and livestock producers come to the table to join, and ultimately lead, the search for solutions.

2.10.1 Introduction

The fourth Intergovernmental Panel on Climate Change (IPCC) report intimated that global climate change has been observed in recent decades. In particular, this change has been characterized by a temperature increase of 0.74 °C (0.56–0.92) over the period 1906–2005 (Meehl et al. 2007). This trend could continue in the coming decades with an unequal distribution across the globe causing a high level of variability, primarily in terms of precipitation and temperature. The Mediterranean basin is one of the regions most vulnerable to plausible alterations in climate (Ewert et al. 2005).

As a sector that is highly dependent on climate and natural resources (water and soil), Mediterranean agriculture is one of the economic sectors under the most serious threat (Iglesias 2008). Changes in climate conditions would have direct consequences on the development of plants (Seguin 2007; Gracia De Cortazar Atauri et al. 2008), agricultural production (Iglesias 2008; Gommes and Balaghi 2009; Reidsma et al. 2010), farmers' incomes (Chabchoub et al. 2010), and natural resources, in particular water (Fischer et al. 2007; Iglesias et al. 2011).

The behavior of agricultural systems to increased variability in temperature and precipitation would not be the same everywhere. This can be explained by the effects of climate on crop yields (Iglesias and Minguez 1997). Vulnerability to climate varies as it is primarily linked to the characteristics specific to each type of agriculture (Anphoux et al. 2003). For instance, an increase in water stress resulting from a reduction in precipitation and an increase in temperatures would probably cause a 16% fall in wheat yields in southern Europe (Olesen and Bindi 2002), while this figure could reach 50% on the southern shores of the Mediterranean (Meehl et al. 2007).

These changing crop yields would be reflected in the instability of farmers' incomes (Reynaud 2008) and disputed responses at both regional and farm levels (Nardone et al. 2010; Reidsma et al. 2010).

The response of the different farms to the variability of precipitation and temperature depends on several biophysical, economic, and institutional factors. From a biophysical point of view, the choice of crop system in relation to the type of soil and climate is a key element at the farm level with regard to increasing the resilience of cereal crops. According to Asseng et al. (2008), reserving cereals (in particular durum wheat) for deep soils with a good useful water reserve is a strategy for reducing the vulnerability of wheat to water stress that is increasingly common during the spring (Asseng et al. 2008). Nevertheless, this strategy may prove insufficient during particularly dry seasons or for irrigated crops such as maize. In such a context, a farmer's investment capacity to install efficient supplemental irrigation systems adapted to the availability and quality of irrigation water is indispensable to offset the yields lost due to climate. Furthermore, two main issues should be considered in assessing resilience and long-term adaptive capacity:

- Short-term objectives aimed at improving resilience are often in conflict with long-term objectives aimed at increasing the long-term adaptive capacity of the farm. For example, the use of drip irrigation to increase water efficiency and combat drought, as seen in various cereal-based systems in the southern part of the Mediterranean region, may gradually increase the concentration of soil salt, thereby reducing the long-term adaptive capacity of the farming system (Belhouchette et al. 2012).
- In many regions, such as the northern Mediterranean, farms have become specialized in either specific livestock or arable farming. These specialized farms, especially dairy farms and arable farms, will probably respond more to climate change than mixed or diversified farms, that is, farms with both livestock and arable production that have more options for change and thus a greater resilience to environmental change.

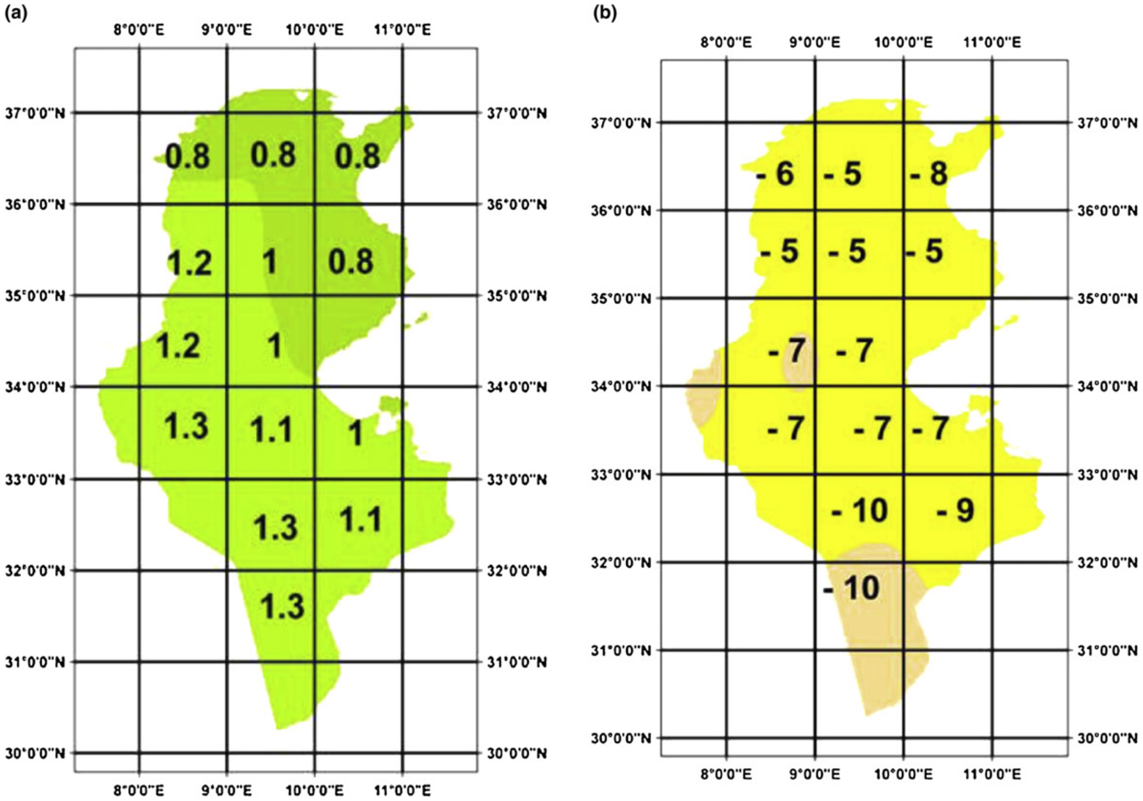

Figure 1 One plausible scenario of (a) increases in annual average temperatures and (b) falls in annual precipitation in Tunisia by 2020. GTZ, 2007: Stratégie nationale d'adaptation de l'agriculture tunisienne et des écosystèmes aux changements climatiques. Cahier 2: synthèse, 13 pp.

Understanding how Mediterranean farms operate in a context of climate means forecasting the change in the farm's environment, in particular in terms of water and soil resources, and assessing the responses of the crop systems to water and heat stress that could become more frequent. Calling on a broad review of the literature, this chapter aims to describe the possible behavior of natural resources, farms and crops systems in light of climate uncertainty. A more detailed analysis will systematically be presented using the case of Tunisia as an example.

2.10.2 Climate in the Mediterranean Region

Located in the southern Mediterranean, Tunisia enjoys a predominantly semiarid and arid climate (Labane 2002). The average annual temperature is between 16 and 22 °C, with a variability between winter and summer (average annual temperatures between 6 and 12 °C and 26 and 32 °C, respectively). (MSP/MEDD 2010).

Figure 1 (GTZ 2007) illustrates one plausible scenario of increases in average temperatures in Tunisia by 2020. Using this map, three average temperature increase zones can be identified: the first zone concerns the north, Cap Bon, and the center-east of the country, with an increase of +0.8 °C; the second is covered by the center of the country with an increase of +1.1 °C; and the third includes southwest and extreme south of the country demonstrating a larger temperature increase (+1.3 °C). The rise in temperature will be more marked by 2050, in particular in the south of the country that will experience a temperature increase of +2.7 °C (GTZ 2007).

2.10.3 The Impacts on Water and Soil Resources

Water resources in the Mediterranean region are already limited in comparison to other countries of the world. The "volume of renewable water resources of all countries of the Mediterranean basin is estimated at 1080 $\mathrm{km}^3\,\mathrm{year}^{-1}$, that is, less than 3% of global resources for more than 7% of the global population" (Milano 2010). Furthermore, a major disparity exists between the countries on the two shores of the Mediterranean due both to the difference in climates and to an uneven distribution of water resources. The northern Mediterranean countries account for 68% of all water resources within the basin compared to 23% in the countries on the southern shores and 9% in the eastern Mediterranean countries (Milano 2010).

Figure 2 illustrates the changing indices for the use of renewable natural resources (defined as the ratio of the annual volume of renewable natural water resources used to the average annual volume of available renewable natural water resources expressed as a percentage) between 2005 and 2025 for all Mediterranean countries. The most serious tension concerning water resources can be observed in the countries of

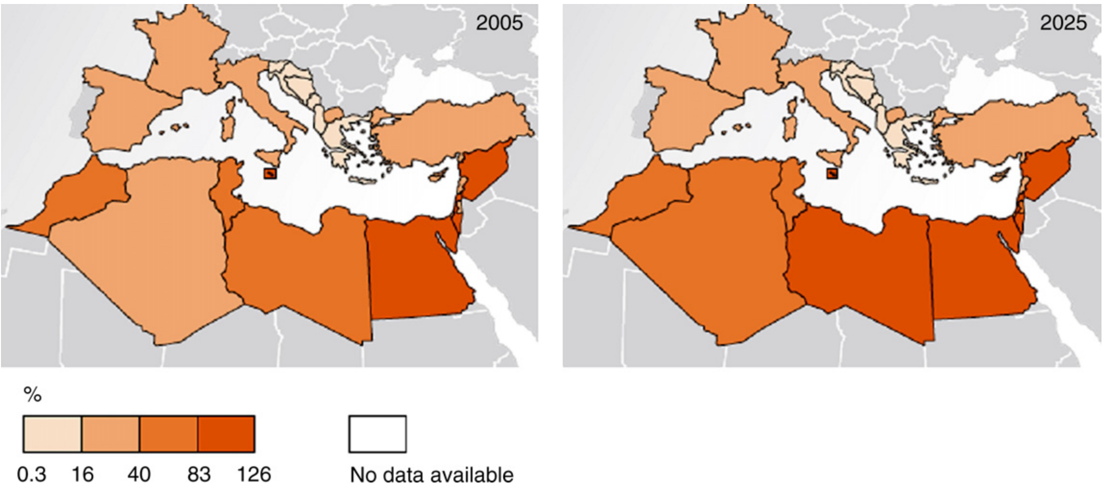

Figure 2 Evolution of the indices for the use of renewable natural water resources in Mediterranean countries (whole countries) for the years 2005 and 2025. An index close to or greater than 75% indicates significant tension concerning water resources, a ratio of between 50 and 75% demonstrates a high risk of medium-term structural tension, while a ratio of between 25 and 50% means that the countries may experience local or cyclical tensions. Pintus, 2009: *Preserving natural resources*. Rethinking rural development in the Mediterranean. CIHEAM. Presses de Sciences Po, 27–57. Using the Blue Plan database.

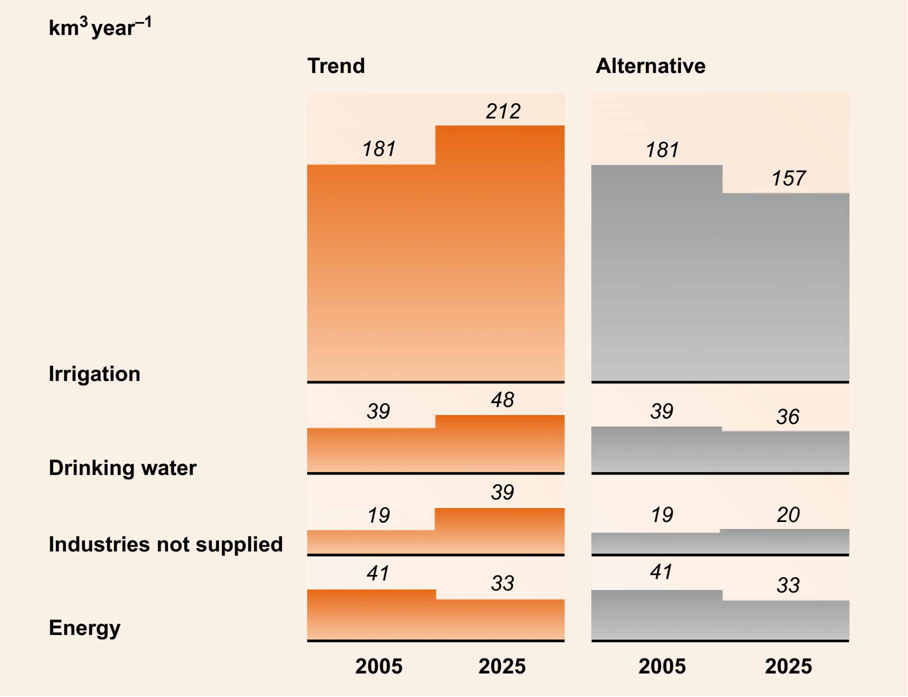

Figure 3 The evolution of water use per sector in the Mediterranean basin for the trend and alternative scenarios between 2005 and 2025. The trend scenario predicts a major increase in problems, whereas the alternative scenario aims at a more sustainable development in relation to the water resource management policies. Pintus, 2009: *Preserving natural resources*. Rethinking rural development in the Mediterranean. CIHEAM. Presses de Sciences Po, 27–57. Using the Blue Plan database.

the southern and eastern Mediterranean, with an index exceeding 50%. Climate effects can exacerbate regional disparities in terms of water resources (Meehl et al. 2007). Alterations in climatic conditions could accelerate the hydrological cycle including changes in precipitation, evapotranspiration, runoff, and the intensity and frequency of floods and droughts (Watson et al. 1996). In Spain, for example, as a result of a plausible temperature increase (+0.4 °C in winter and +0.7 °C in summer) and a reduction in precipitation, a 17% reduction in the availability of water at the national level is forecast. The effects of these changes would be even greater in southern Spain with a fall of up to 34% (Iglesias et al. 2007).

This climate pressure is compounded by:

- An estimated 18% increase in the demand for renewable water resources by 2025 (Antipolis 2008);
- A constantly increasing population, in particular, in the countries of the southern and eastern Mediterranean. It is estimated that the population will increase by 100 million people to reach 340 million inhabitants by 2025 (Benblidia and Margat 2008);
- Increased competition for water resources among the different users, in particular, during the summer when demand is high and resources scarce, notably in the southern and eastern Mediterranean. Figure 2 illustrates the estimated water use per sector in two different scenarios (trend and alternative) for the year 2025.

In the Mediterranean, agriculture is one of the sectors that consumes the most water. The use of water in agriculture exceeds 60% in Algeria, Tunisia, Mauritania, Spain, Greece, and so on, compared to 15% total use in France (Milano 2010). According to Fischer et al. (2007), water requirements for irrigation purposes would increase in the wake of both socioeconomic development and plausible climatic conditions over the coming decades.

Tunisia is considered a water-poor country with a ratio of 480 m^3 $inhab^{-1}$ $year^{-1}$ (below the water poverty threshold of 500 m^3 $inhab^{-1}$ $year^{-1}$). This ratio will fall to 360 m^3 by 2030 when the population will have risen to 13 million inhabitants (Louati 2011).

Water resources available in Tunisia are divided between surface water (51%) and underground water (49%). These resources are unevenly distributed across the country. Table 1 illustrates the regional distribution of potential water resources in Tunisia for 2008. Surface water resources diminish as we travel from north to south. The majority of surface water comes from the northern basins (Medjerda), which provide a relatively large and regular supply; while the central and southern regions of the country boast a large potential of underground resources (groundwater and deep water), which, nevertheless, demonstrate a low renewal level and a high level of salinity (Mekki 2010). A total of 87% of groundwater has a salinity of over 3 g l^{-1} (Lahache 2007).

Using the future strategic orientations for the water sector, it has been possible to compare demand and supply in 2020, 2030, 2040, and 2050 under a subset of plausible future conditions (MARH 1998; GTZ 2007). Figure 4 illustrates scenarios of the resources/demand for resources balance. Thanks to the resource mobilization efforts accompanied by recourse to nonconventional resources and a water-saving policy, the study has shown that the resources/demand balance would remain in surplus in 2040 for an average scenario. From 2050, the situation would become more critical, if these scenarios are correct, particularly in central and southern Tunisia, as water requirements will be more or less equal to the resources available. Moreover, government strategies may be sustainable in the medium term but not in the long-term under this set of plausible future conditions.

Table 1 Regional distribution of potential water resources in Tunisia in millions of m^3

		Underground water		
	Surface water	*Ground water*	*Deep water*	*Total*
North	2185	388	285	2858
Center	290	237	220	747
South	225	115	885	1235
Total	2700	740	1400	4840

MARH, 1998: Eau 21: stratégies à long terme du secteur de l'eau en Tunisie (2030). *Direction des ressources en eau de Tunis.*

Climate (temperature and precipitation) effects for Tunisia, if there is a warming and drying, would increase the water vulnerability of the country with disparities between the north, the center, and the south of the country. Surface and underground water could plausibly diminish by 5 and 28%, respectively, by 2030, leading to a reduction in water available for use. In the event of a lack of water, the agricultural sector will be the first to be affected by the shortage as agricultural needs represent 81% of resources. This lack of water could total 50% of needs (Lahache 2007).

In northern Tunisia, a 9.3% increase in evaporation would probably lead to a fall in water supplies in reservoirs of approximately 1%. Changes in seasonal precipitation could lead to less frequent silt clearance and thus to a 5% reduction in storage capacity by 2030. In central and southern Tunisia, the increased needs of the agricultural sector resulting from an increase in temperature and a reduction in precipitation would lead to the overuse of underground water resources as well as deterioration in the quality of the water (Lahache 2007).

The deterioration in the quality of irrigation water coupled with reduced precipitation and increased evaporation of water in the spring and early summer would result in a low level of soil humidity in summer and, thus, an increased risk of drought as well as an increase in soil salinity. The Mediterranean region is vulnerable to soil salinity, in particular in the southern and eastern regions (Figure 5).

In regions where the climate is arid or semiarid, soil salinity is essentially linked to irrigation (Pintus 2009). The problem of soil salinity primarily concerns irrigated areas. For instance, the salinity observed in 1995 in the irrigated areas of the lower Medjerda Valley (northern Tunisia) shows that 28% of the soils exceed the critical level of salinity of 4 ds m^{-1}. This problem of increased soil salinity is exacerbated by the absence of drainage networks and the use of irrigation techniques, which are often not suited to the type of soil or the crop cultivated, thereby causing an accumulation of salt around the roots of plants and thus a significant fall in yield, in particular for the crops most sensitive to salinity (market gardening, maize, etc.) (Abbes 2004). Table 2 illustrates the yield of two crops relatively sensitive to soil salinity (maize and tomatoes according to two different types of soil in terms of both the texture and salinity of the soil). Soil salinity causes a fall in maize and tomato yields of 21 and 47%, respectively.

If the regional climate changes, an increase in soil salinity caused by reduced precipitation and more frequent droughts could occur. In his study on the assessment of the sustainability of Mediterranean production systems, Belhouchette (2004) demonstrated that the drier the climate, the greater the soil salinity. Furthermore, soil salinity is higher when precipitation

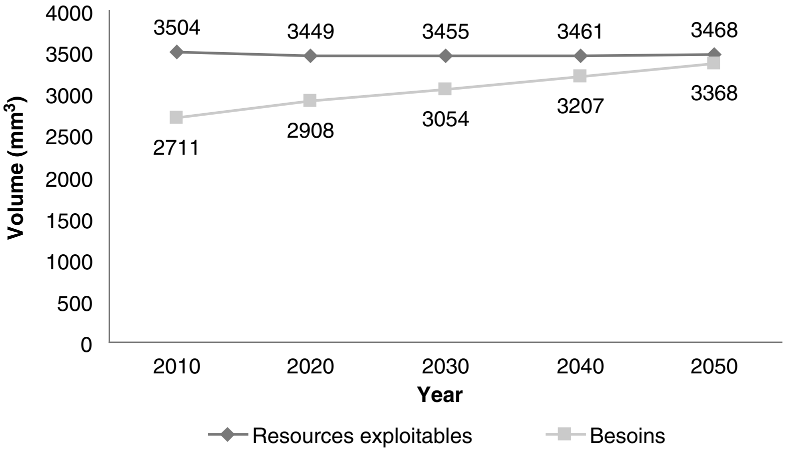

Figure 4 Forecast available/required water resources balance in 2050, ignoring the effects of climate change, in a scenario of average resources available and average needs. GTZ, 2007: Stratégie nationale d'adaptation de l'agriculture tunisienne et des écosystèmes aux changements climatiques. Cahier 2: Synthèse, 13 pp.

Abbes, K., 2004: Analyse de la relation agriculture environnement: une approche bio-économique. Cas de la salinisation des sols et de la pollution par les nitrates au nord tunisien. Thèse (Dr. d'Université), Faculté des sciences économiques, Université Monpellier I, 313 pp.

is low (Belhouchette 2004). For example, in the CEBALAT irrigated area (northern Tunisia), an increase in the accumulation of salt in the soil is predicted following the increase in water stress (Figure 6).

Nevertheless, the effect of soil salinity is not always linear from 1 year to the next (Belhouchette 2004; Belhouchette et al. 2012). A farmer's capacity to adjust his production activities in terms of the choice of crop and the choice of

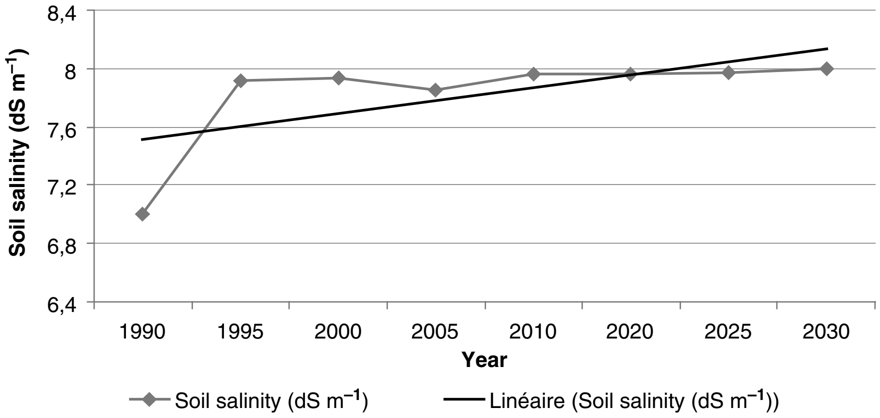

Figure 6 Forecast change in soil salinity until 2030 in the CEBALAT irrigated area (northern Tunisia). Belhouchette, H., 2004: Evaluation de la durabilité de successions culturales à l'échelle d'un périmètre irrigué en Tunisie : utilisation conjointe d'un modèle de culture (Cropsyst), d'un SIG et d'un modèle bio-économique. Thèse (Dr. d'Université en Sciences Agronomiques), ENSA-Montpellier, 155 pp.

irrigation and rotation techniques can cause a reduction in soil salinity.

2.10.4 Farmers' Responses to Climate

Farmers have always responded to socioeconomics, institutions, and climate through improved farm management by adjusting their cropping or production systems. In the coming decades, farmers may have to overcome the double challenge of ensuring the economic and ecological viability of their farms while coping with possible new climate conditions. In addition to the direct impacts on the cropping systems caused by climate uncertainty, they will also be faced with pressure on the availability of, demand for, and accessibility of natural resources, in particular water (Wei et al. 2009).

Nevertheless, the impacts of these climate and socioeconomic changes cause variable impacts according to the biophysical, institutional, and socioeconomic context. More particularly, a high level of variability of cropping system responses to the irregular precipitation and temperatures would almost certainly lead to a disparity in the farmers' responses (Reidsma et al. 2010). The heterogeneity of farmers' responses can be explained by both the structure of the farm (size, technical-economic orientation, etc.) and the related performance indicators (net margin, intensification rate, etc.). The impacts of these factors cannot, however, be generalized as they are very different from one region to another (Reidsma et al. 2009; 2010). In the Mediterranean context, analyzing farmers' responses means taking a complex set of farmers' decisions into account according to both the biophysical (climate, soil, cropping system) and the socioeconomic contexts (prices, quotas, subsidies, etc.) (Belhouchette et al. 2012), which differ between region.

Furthermore, an analysis of the interactions between farm characteristics and the impacts of climate revealed different behavior in the different regions. Farms that appeared to be the least vulnerable to external shocks (economic and agronomic performances) do not necessarily enjoy greater adaptability to climatic conditions (Challinor and Wheeler 2008; Reidsma et al. 2010). Small-scale traditional farms, for example, may enjoy a better capacity for adapting to climate than large-scale intensive farms. Figure 7 illustrates the correlation between farm characteristics and the impacts of temperature on production in different European countries (Reidsma et al. 2010). In France, small-scale farms demonstrate a greater capacity for adapting to climate, whereas this does not hold for either Spain or Greece where the impacts of temperature on production are positively correlated with the economic scale of the farm (Reidsma et al. 2010).

In northern Tunisia, and more particularly among the farms of the lower Medjerda Valley, the farms that succeed in maintaining their income without altering their current operating methods are those characterized by diversified cropping systems based essentially on arable crops, forage crops, and market gardening with a very significant livestock activity. They enjoy greater room for maneuvering through the adjustment of their production activities and the choice of irrigation doses applied as well as more profitable rotations, for example, increasing the area allocated to cereals that are less sensitive to water stress, such as barley and forage crops, at the expense of winter wheat (Figure 8). Farms specializing in tree crops, however, are the most sensitive to climate due to a lack of flexibility at farm level and the high cost of lifting the trees (Chabchoub et al. 2010).

However, short-term objectives aimed at improving farm profitability are often in conflict with long-term objectives concerning the reduction of soil salinity. Figure 9 demonstrates the economic and environmental impacts of farmers' decisions (rational/not rational). The application of rational irrigation doses will certainly cause the farmer's income to fall in the short-term but will be conducive to an increase in the farmer's income in the long-term, while ensuring a relatively low increase in salinity levels. On the other hand, a farmer aiming to maximize income by means of high irrigation doses will eventually find that his soil has a high salt content which will affect crop yields and cause a subsequent fall in the farmer's income (Belhouchette et al. 2012) (Figure 9).

Furthermore, if we consider the assessment of climate at farm level, it is the farm characteristics that explain the variability of its performances. Nevertheless, due to the diversity of

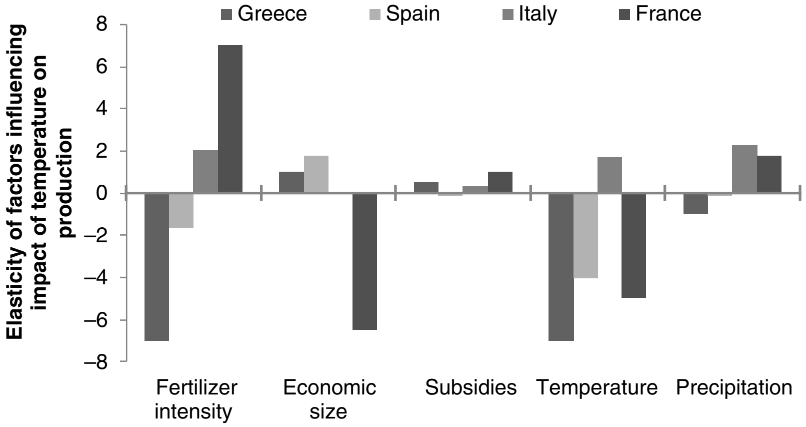

Figure 7 Influence of farm characteristics, climate conditions, and socioeconomic conditions (see Table 1 for a description) on reducing or exacerbating the impacts of higher temperatures on production (temporal variability including interactions, regional level). Reidsma, P., Ewert, F., Alfons, O. L. and Leemans, R., 2010: Adaptation to climate change and climate variability in European agriculture: the importance of farm level responses. *Eur. J. Agron.*, **32,** 91–102, http://dx.doi.org/10.1016/j.eja.2009.06.003.

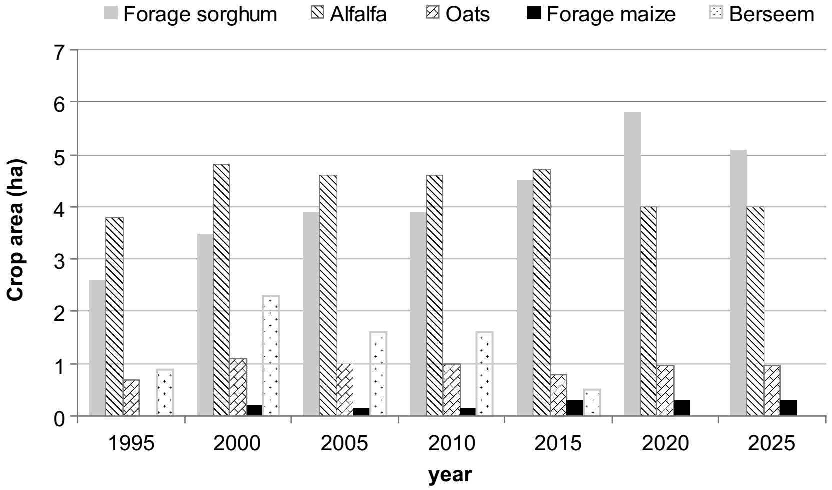

Figure 8 Evolution of the area reserved for each crop in the CEBALAT irrigated area (northern Tunisia). Belhouchette, H., 2004: Evaluation de la durabilité de successions culturales à l'échelle d'un périmètre irrigué en Tunisie : utilisation conjointe d'un modèle de culture (Cropsyst), d'un SIG et d'un modèle bio-économique. Thèse (Dr. d'Université en Sciences Agronomiques), ENSA-Montpellier 155.

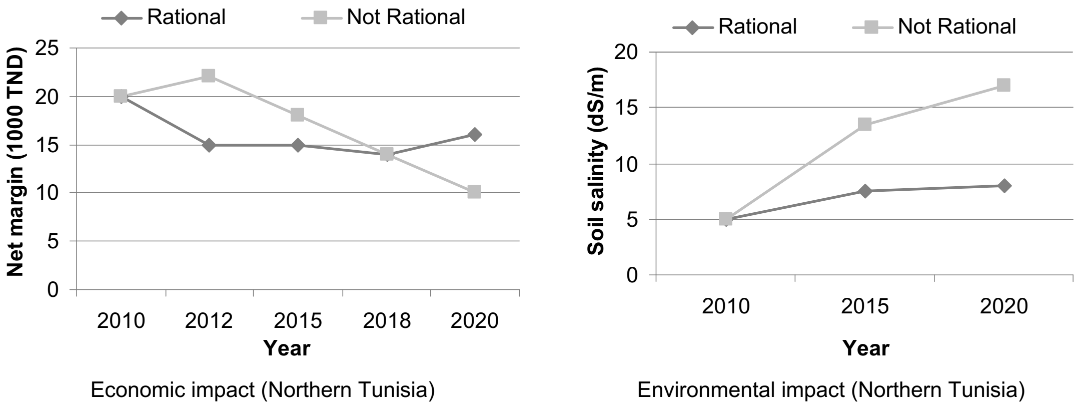

Figure 9 The economic and environmental impact of a farmer's decision concerning irrigation doses (rational and not rational) over 10 years. Belhouchette, H., 2004: Evaluation de la durabilité de successions culturales à l'échelle d'un périmètre irrigué en Tunisie : utilisation conjointe d'un modèle de culture (Cropsyst), d'un SIG et d'un modèle bio-économique. Thèse (Dr. d'Université en Sciences Agronomiques), ENSA-Montpellier, 155 pp.

farms in terms of their structure and performances, the possible adaptations cannot be generalized. It would probably be more profitable, for example, for maize areas in France, as it is a crop that consumes a great deal of water, whereas this strategy would have no major impact on farmers' incomes in other regions (Reidsma et al. 2010). In addition to the variability of maize yields, other factors also play a role in explaining farm performances (agricultural policies, etc.).

2.10.5 The Effects on Cropping Systems

2.10.5.1 The Effects on Crop Water Requirements

In a context of climate, crops are subjected to stress factors that can affect their water requirements, growth, development, and yields (Iglesias and Minguez 1997; Reidsma et al. 2009). The impacts generally depend on the biophysical conditions in each country, the characteristics and particularities of each type of agriculture and the type of crop (Anphoux et al. 2003). Climate factors, in particular precipitation and temperature, have direct effects on the growth of crops. **Figure 10** illustrates the changing water requirements for maize (Midi-Pyrénées class, France), which have risen from 150 mm in 1993 to 300 mm in 2005 under the effect of increasing evaporative demand, with an average of 230 mm (Teyssier 2006). These requirements reached 400 mm in 2003, which was a particularly dry year, especially during the summer. The maximum temperature recorded during the summer in this region was 43 °C (**Figure 10**).

Furthermore, an increased frequency of hot days, in particular during winter and spring, and highly irregular precipitation would probably give rise to an increased water requirement for crops, especially spring and summer crops (e.g., maize), as well as for rain-fed crops such as winter cereals. Studies concerning possible changes in regional climate in the Mediterranean region anticipate increased water demand for spring crops of between 2 and 4% for maize, 6 and 10% for potatoes (PNUE/PAM 2009), and 8 and 10% for winter wheat (Supit et al. 2010).

The water consumption of crops depends on the water retention capacity of the soil and the crops' water requirements (Supit et al. 2010). In the case of the summer crop sugar beet, for example, Supit et al. (2010) demonstrated that the water deficit calculated as the difference between water requirements and water consumption is primarily observed in Mediterranean countries that typically experience hot and dry seasons where the soil is less well-suited to this type of crop. A water deficit of between 14 and 30 mm year^{-1} was recorded in Italy and Greece.

In northern Tunisia, the current irrigation amounts used are insufficient for irrigated summer crops if there is a warming and drying. In the case of maize, for instance, increasing water requirements could reach 58%. It is therefore a question of the irrigation techniques applied by farmers. Concerning rain-fed winter crops, supplemental irrigation is necessary during the sowing period and in spring. **Figure 11** illustrates the water deficit for durum wheat in northern Tunisia between the crop's water requirements and effective rainfall. Water deficit could reach 150 mm in May.

2.10.5.2 The Effects on the Crop Development Stages

Research works confirm that crops positively react to increased concentrations of CO_2 if other aspects of climate do not change (Jablonski et al. 2002), whereas the impacts associated with high temperatures, the intra- and interannual variability of precipitation and possibly the increased frequency of extreme events such as droughts and floods would probably reduce crop yields and increase the risks of a fall in production (Fischer et al. 2007). There are a number of reasons why climate can influence yields both positively and negatively. First, an increase in temperature would shorten the phenological phases. In Spain, for example, the lengths of the growth period of maize could plausibly decrease by 7–21 days (Iglesias and Minguez 1997). This

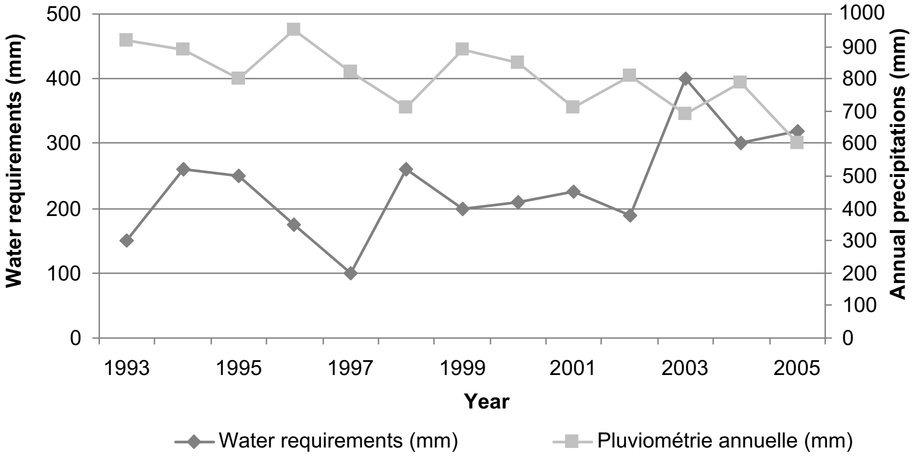

Figure 10 Changing water requirements of Midi Pyrénées-class maize (France) and annual precipitation in millimeters over the period 1993–2005, with an average of 230 mm. Teyssier, F., 2006: Les consommations d'eau pour irrigation en midi-Pyrénées. Surfaces irriguées et volumes d'eau consommés: Rapport avec le climat, la PAC, les ressources sur la période 2001–2005. would reduce the time for light and water capture and would reduce water and light use. A simultaneous decrease in precipitation would reduce water availability. Accelerated crop development and a short grain-filling period would reduce grain yield, for example with a plausible fall of about 24% for wheat in Spain (Iglesias and Minguez 1997), whereas the additional carbon available will create an initial yield increase because of increased light and water use efficiencies. For instance, an increase of CO_2 ($+600\ \mu mol^{-1}$) leads to a 30 and 8% increase in wheat and maize yield, respectively, in Spain (Iglesias and Minguez 1997).

Several studies have analyzed the changes observed at the crop development phase level. In the Mediterranean basin, where water availability is already limited, in particular in the south and east, an increased summer temperature would have the effect of shortening the growth period of the crops, thereby offering less time to accumulate biomass (Rosensweig and Tubiello 1997). In the case of annual crops in Morocco, for example, the time between sowing and harvesting could be reduced causing a shortening of the growth period of 70 days (Benaouda and Balaghi 2009).

Perennial crops are also affected by these phenomena. Following a temperature increase, the phenological stages of fruit trees would be brought forward causing a deterioration of the intensity of flowering resulting from the reduction in cold episodes (Benaouda and Balaghi 2009). Figure 12 illustrates the changing harvest date for the BANYULS *cépage* (*cépage*: The BANYULS *cépage* is a variety of vine very common in the northern Mediterranean region) for the period 1990–07 in the Midi-Pyrénées region (France). Over 17 years, the harvest date has moved forward by about 15 days on average. These changes to the growth cycle of the crops will probably have a direct effect on crop yield.

The response of agricultural systems to climate also depends a great deal on farming practices (the amounts and frequency of irrigation and fertilizers) (Tubiello et al. 2000). In conditions where water is limited, for example, the effect of high concentrations of CO_2 is positive in relation to conditions where the crop is well watered (Chaudhury et al. 1990; Kimball et al. 1995). When the nitrogen inputs are high, the crop responds more positively to CO_2 than crops with less fertilizer (Sionit et al. 1981; Mitchell et al. 1993).

For the Tunisian case study, Table 3 summarizes the average and standard deviation of the duration of each phenological stage and the duration of the overall growing season for two strategic cropping systems for the Mediterranean region such as Tunisia: wheat and maize.

Table 3 Summary of the average and standard deviation of the duration of wheat (sowing date 18 December) and maize (sowing date 2 April) phenological stages and the length of the growing season calculated from 1995 to 2025

			Flowering	*Grain filling*		
		Emergence	*Days after sowing*		*Maturity*	*Length (day)*
Wheat	Mean	25	96	120	148	164
	SD	2.6	2.5	2.6	3.2	3.2
Maize	Mean	14	53	61	115	116
	SD	1.7	3	3.4	8.5	8.5

Temani, N., 2010: Assessing wheat and maize cropping systems responses to the uncertainty of climate change: Application to an irrigated area in Northern Tunisia. Mémoire de fin d'études, SUPAGRO et IAMM, 43 pp.

From 1995 to one scenario for 2025 a slight variation in the duration is observed during emergence, flowering maturity, and grain filling for wheat and maize. In both cases, the highest variability occurs during the maturity phase with a standard deviation of 3.2 days for the two cropping systems.

Table 3 shows that from 1995 to a plausible scenario for 2025, maize emergence occurs 14 days (±1.7 day) after sowing. Anthesis and grain filling require 53 days (±3 days) and 61 days (±3.4 days) respectively, while maturity varies by 5.5 days. The phenological stages would occur earlier and crop seasons would be shortened (Iglesias and Minguez 1997). In this study, we calculate a change of 8.5 days in the length of the growing season, simulated under higher atmospheric CO_2 concentration, increased temperature, and altered precipitation.

2.10.5.3 The Effects on Crop Yields

The impacts of climate on crop yields are generally estimated by means of biophysical models using climate data produced by regional circulation models or general circulation models, or by experimental data. These yield a subset of plausible regional climate conditions in the coming decades. A certain number of crop simulation models, such as CERES-Maize (Crop Environment Resource Synthesis), CERES-Wheat, SWAP (Soil–Water–Atmosphere–Plant), CropSyst (Stöckle et al. 2003), and InFoCrop (Aggarwal et al. 2006), have also been widely used to assess the possible impacts of climate on agricultural production, and more particularly to analyze the sensitivity of crop yields to the different climate scenarios.

Using a subset of plausible climate scenarios in the Mediterranean basin (Meehl et al. 2007), crop yields would be subject to major change. These changes are not homogeneous and depend on the phenology of the crops, the type of crop (e.g., C3 or C4), and the environmental conditions (the availability of water and nutritive elements) (Antipolis 2008). Agriculture in the southern countries would probably be more affected by these effects. Several works have focused on studying the variation in crop yields for the different IPCC scenarios. The results obtained for these different studies predict that rain-fed crops would be directly affected by climate change. In Italy, for instance, an increase in air temperatures would accelerate the phenology of the plants, thereby reducing the accumulation of dry matter and reducing wheat yields by between 30 and 50% (Tubiello et al. 2000). In Australia, the reduction would be 15% (Ludwing and Asseng 2010). Applying the CROPWAT model (Food and Agricultural Organization) to winter cereals in Morocco shows a reduction in yield of 10% in a normal year and of 50% in a dry year by 2020 using the IPCC subset of plausible scenarios as well as a 30% fall in national production. In Algeria, average reductions in crop yields of between 6 and 14% are simulated.

The IPCC scenarios also show an effect on vegetables, with a productivity variation of between –30 and +5% simulated for 2050. In Algeria, vegetable yields are predicted by the IPCC models to decrease by between 10 and 30%. This fall would reach 40% in Morocco by 2030 according to these models (PNUE/PAM 2009).

An occurrence of extreme events during the crop development cycle (rain during sowing or drought during flowering) or more intense precipitation and longer droughts would also reduce summer crop yields. In addition to the effects of climate, other factors can cause crop yields to fall, such as the appearance of new pests and parasites (PNUE/PAM 2009). In Italy, for example, the yield of sorghum, which is a summer forage crop, could fall by between 10 and 30% (Tubiello et al. 2000).

For the Tunisian case, a study is conducted by Temani (2010) in the CEBALAT catchment area (northern Tunisia) to determine the behavior of maize and wheat in a context of climate. To this end, 30 years of weather data were analyzed in order to define the precipitation scenarios most closely matching that of the Cebalat region (an average precipitation of 470 mm). Inter- and intraannual variability led to high standard deviations. Three rainfall patterns are chosen based on rainfall probability: dry, average, and wet years (with probabilities of 30, 50, and 20%, respectively).

Simulated grain yield in the three precipitation scenarios shows a decrease of 25% between average and dry years, while the same rate of decrease is maintained for the difference in the Above Ground Biomass (AGB) in these 2 years (Figure 13). A sensitivity analysis was conducted to test the effect of the variety's sensitivity to water stress on grain yield. A tolerant variety produces 300 kg ha^{-1} of grain more than a sensitive variety.

As mentioned in Figure 13, the dry year has the lowest grain yield; therefore, the water, temperature (Figure 14), and salinity stress occurring during the wheat growing season of the dry year was monitored. No water stress appears throughout the entire growing period. Salt accumulated in the top meter does not exceed 1 dS m^{-1} while heat stress occurs from the beginning of the vegetative period to the grain-filling stage (Figure 14). It has already been reported that grain yield is

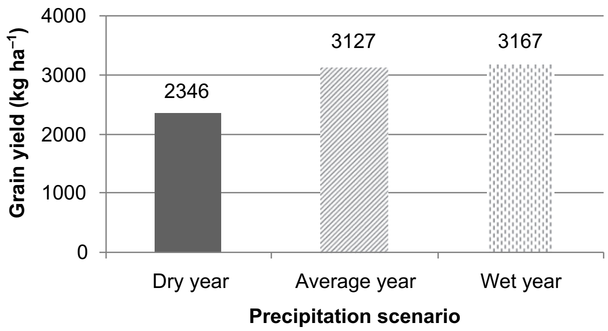

Figure 13 Simulated wheat grain yield obtained in the three precipitation scenarios. Temani, N., 2010: Assessing wheat and maize cropping systems responses to the uncertainty of climate change: Application to an irrigated area in Northern Tunisia. Mémoire de fin d'études, SUPAGRO et IAMM, 43 pp.

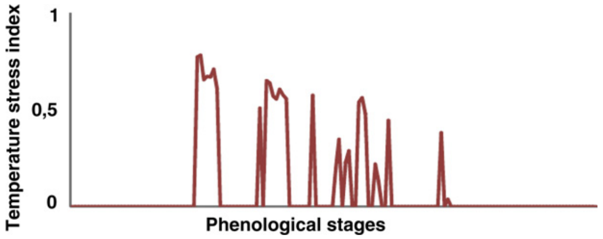

Figure 14 The evolution of the temperature stress index during the dry year wheat growing season. Temani, N., 2010: Assessing wheat and maize cropping systems responses to the uncertainty of climate change: Application to an irrigated area in Northern Tunisia. Mémoire de fin d'études, SUPAGRO et IAMM, 43 pp.

negatively correlated to maximum temperature (Wang et al. 2006). Gate (1995) highlighted that some extreme temperatures occurring in specific phases of development may lead to an additional fall in grain yield. In Figure 15, therefore, the maximum temperature distribution is examined during the accumulation of wheat AGB in the dry year to detect if such a phenomenon occurs.

In active growth, the maximum temperature exceeded 22 °C for 5 days. Gate's experimental data (1995) has shown that the optimum temperature during this phase is 12 °C. Beyond this optimum, the number of fertile flowers gradually decreases as the temperature rises. This confirms Wang et al.'s (2006) observation that a temperature exceeding 23 °C occurring during the reproductive period significantly reduces grain yield.

During grain filling, the optimum temperature to achieve maximum kernel weight is 15–18 °C. Warmer temperatures up to 30 °C mainly affect assimilate availability, translocation of photosynthates to the grain, and starch synthesis and deposition in the developing grain. This leads to a lower grain yield due to lower thousand-grain weight (Modhej et al. 2008). For the Tunisian dry year simulation, temperature during the grain-filling phase in 2019 ranges from 18 to 31 °C, generating heat stress expressed by a value of 0.5 on the temperature stress index. Figure 15 shows severe heat stress during the early growth stage. In addition, the wheat cutoff temperature is 25 °C. In the dry year, the temperature exceeds 25 °C on 19 days, reaching a maximum of 33 °C where growth stoppage is possible.

Figure 16 shows that maize grain yields from 1995 to 2025 are very low compared to other regions. This large difference between yields is due to the fact that maize is generally sown in spring in the northern part of the Mediterranean, whereas in the Tunisia case it is a summer crop sown in July giving a simulated grain yield of 4 tons ha^{-1}.

The highest yield is obtained in 2010 (3 tons ha^{-1}), while the lowest was that of 2003 with a yield 66.2% lower. In order to explain the main reasons for such a drop in yield, the curves of water stress, heat stress, and soil salinity observed during the maize growing season are presented in Figure 17, which shows that heat stress occurred from flowering to maturity. The temperature stress index reached a maximum of 0.9 in the grain-filling phase, which is very sensitive to temperature. In general, the grain-filling rate decreases as mean temperature drops (Wilkens and Singh 2001). Furthermore, severe water

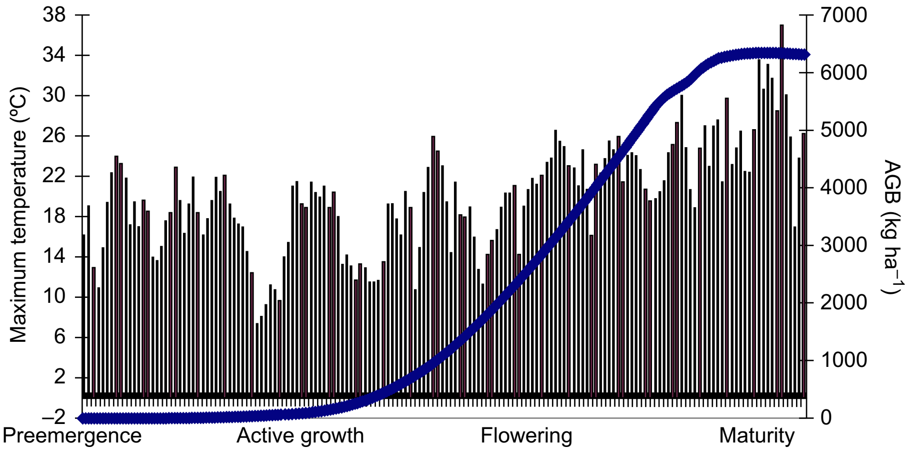

Figure 15 Simulated maximum temperature during AGB accumulation during the dry year. Temani, N., 2010: Assessing wheat and maize cropping systems responses to the uncertainty of climate change: Application to an irrigated area in Northern Tunisia. Mémoire de fin d'études, SUPAGRO et IAMM, 43 pp.

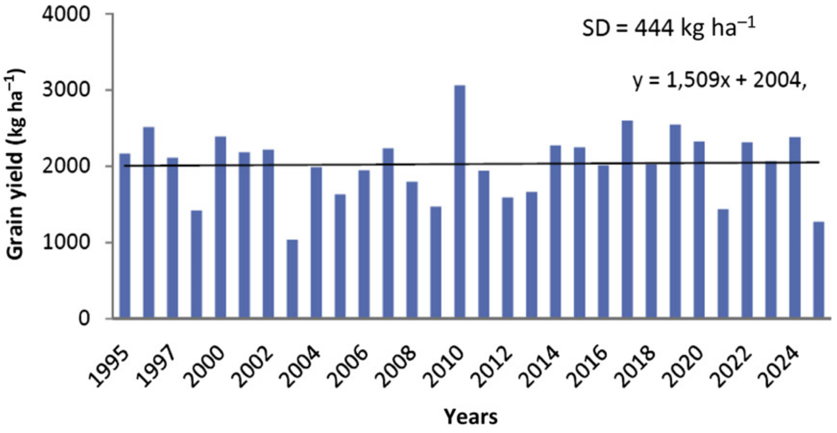

Figure 16 Simulated annual maize grain yield for the period 1995–2025. Temani, N., 2010: Assessing wheat and maize cropping systems responses to the uncertainty of climate change: Application to an irrigated area in Northern Tunisia. Mémoire de fin d'études, SUPAGRO et IAMM, 43 pp.

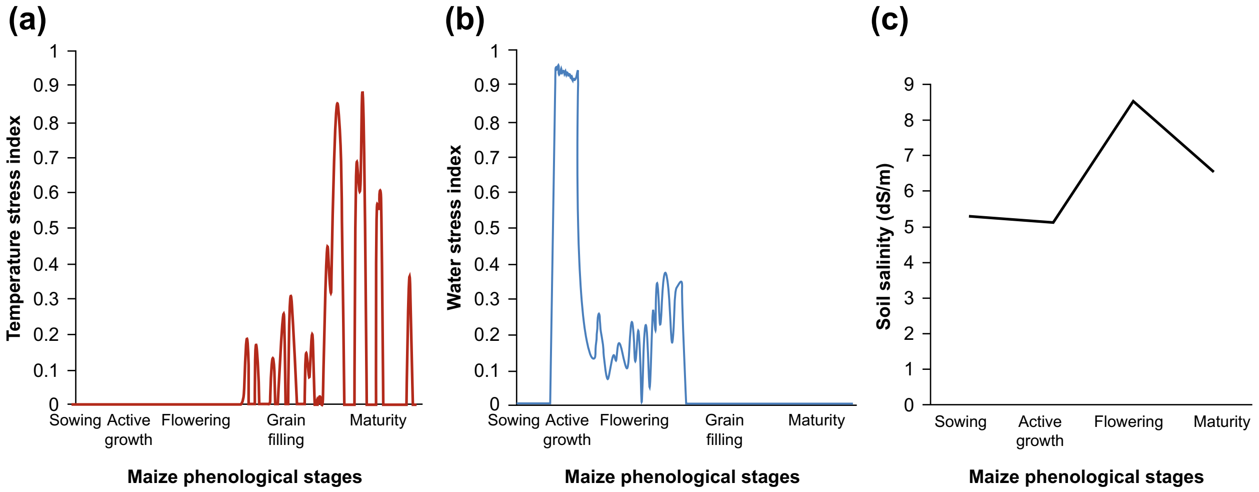

Figure 17 Evolution of types of stress during maize growth in 2003. Evolution of (a) the temperature stress index, (b) the water stress index, and (c) the average soil salinity in the top meter during the maize growing season. Mémoire de fin d'études, SUPAGRO et IAMM, 43 pp.

stress (water stress index = 0.9) was observed during active growth, which is a very critical and sensitive period for water storage (Gate 1995). Water stress continues to a lesser extent until grain filling, increasing the risk of compromising the grain yield. Despite irrigation, maize still suffers from water stress. This is probably due to the high soil salinity that reached 8 dS m^{-1} during the flowering stage. Thus, salinity, water stress, and heat stress led to the low yield obtained in 2003. However, water stress seems to be the main reason behind this result. In 2010, despite high salinity and temperature stress, yields were 66% higher than in 2003 (Figure 18).

2.10.6 Conclusion

Mediterranean agriculture is a sector that is particularly sensitive and vulnerable to climate (Ewert et al. 2005). Increased variability of precipitation and temperature would have several impacts (both positive and negative) on natural resources, the crop development cycle, crops yields, and farmers' incomes while demonstrating regional disparities. The impacts of climate on the agricultural production systems are the result of complex and strongly contrasting mechanisms, which are closely linked to the institutional, socioeconomic, and geographic situations of each country. The most unfavorable regions are not necessarily the most vulnerable to climate variability (Challinor et al. 2009; Reidsma et al. 2010). For instance, in the Mediterranean basin, the diversity of farms in terms of size and intensification rates reduces the regional vulnerability of wheat yields (Reidsma and Ewert 2008). Furthermore, the diversification of farms could be a strategy for adapting to the variability of temperatures and precipitation. In this context, others' adaptations can be recommended to reduce the negative reactions of crops to climate (e.g., adopting specific farming conduct methods: modification of sowing dates, etc.). However, "these methods could require up to 40%

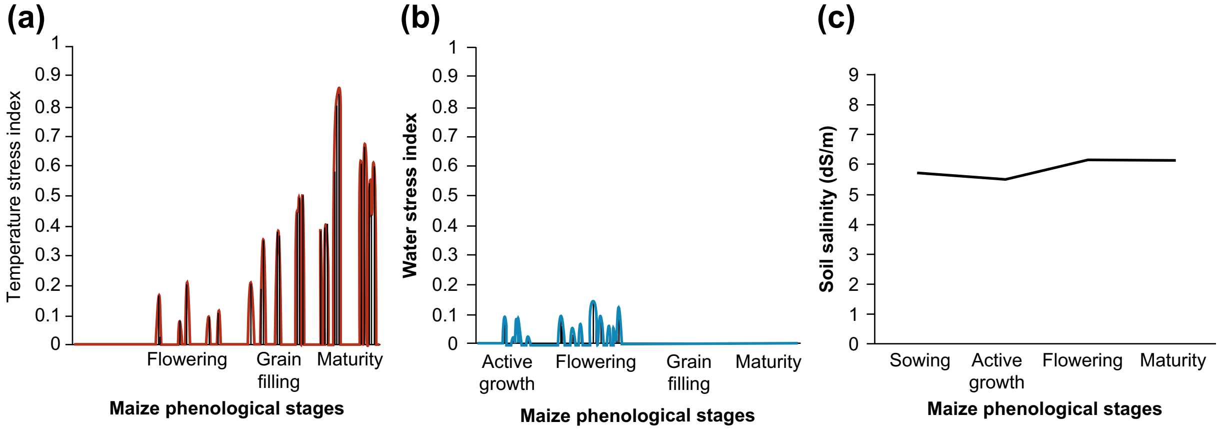

Figure 18 Evolution of types of stress during maize growth in 2010. Evolution of (a) the temperature stress index, (b) the water stress index, and (c) the average soil salinity in the top meter during the maize growing season. Mémoire de fin d'études, SUPAGRO et IAMM, 43 pp.

more water for irrigation, a volume of water which could prove essential in certain regions in the future" (PNUE/PAM 2009). Adaptation strategies cannot therefore be generalized and depend on the biophysical, socioeconomic, and political characteristics of each region. An increased number of specific studies must be conducted for each region to assess the resilience of the production systems and the possible adaptation strategies.

Determining the responses of the cropping and farming systems to climate as well as the possible adaptation capacities means taking account of the different elements that can affect farmers' decisions with regard to the environment of the system (socioeconomic, political and institutional, biophysical) and the characteristics of the biophysical systems (soil types, technical choices, etc.).

Several prospective studies indicate that, in addition to water scarcity and quality, several drivers will make the Mediterranean agricultural systems more vulnerable:

- The Mediterranean Region (MR) population is increasing (expected to increase from 446 million in 2000 to 579 million in 2025) and the region is characterized by important movements of population due to economic and social reasons or even to local conflicts. The economy tends to be more global and the ways of life more uniform, particularly in terms of food and leisure, which is strengthening the relations between urban and rural areas (Pintus 2009).
- Climate already modifies the physical and biological environment of agriculture in the MR: an increase in average temperature and decrease in precipitations, invasions by new pests and weeds, higher frequency of extreme events (drought, flooding, heat, storms,…). It tends to reduce the availability of water, increase risks (losses in yield and livestock, erosion,…), and threatens the sustainability of most farming systems.
- Public policies aim at increasing agricultural production, reducing poverty, and limiting migration to cities or abroad. They tend to concentrate agricultural production in regions where the prevailing farming systems tend to specialize in few crops and animal products of high added value, thereby stimulating the intensive use of water, chemicals, and soil resources. In the margins, small farms survive with a lower availability of resources and a more intensive use of labor, often by combining incomes from different sources (agricultural and nonagricultural activities, emigration).
- Local organizations are rarely neutral with regard to local development process and particularly agricultural production. They may facilitate local actors' representations in the decision-making process; they may also reflect conflicts of interests between different groups of actors. But they may also bring knowledge and innovations that could be meaningful at a higher level. In all cases, they take part in the regional development process. This is still rarely studied in the southern part of the Mediterranean basin, where local development is being implemented since the year 2000.

In this context, the challenge is to develop methods and tools allowing one to assess the vulnerability of Agricultural Systems of the MR, to these policies where economic and climatic impacts simultaneously occur. This question should be addressed with regard to the diversity of the contexts (institutional, socioeconomic, and environmental) and of the farming systems.

Scaling between different organization levels and integrating visions and options from a range of disciplines (e.g., agronomy, ecology, economic, and sociology) (Van Ittersum et al. 2008) are then vital for a sufficiently broad perspective on vulnerability and adaptive strategies of agricultural systems. One of the obstacles to the operational integration of different disciplines is the variety of formalisms, which is, for example, reflected in the models and the 'preferred' scales of analysis in the research projects of each discipline. As a result, different research groups of the MR have developed projects with similar aims but with incompatible software tools and a lack of analysis of the interactions between social, environmental, and economic systems. Models, data, and methods (scenario, indicators, typologies, scaling methods, etc.) are generally less generic than they are aimed for, and the conditions of their reusability in a new MR are poorly defined.

2.11.1 Introduction

Wetlands are essential ecological components of landscapes that provide numerous socioeconomic and ecological services. The global distribution of wetlands is shown in Figure 1. Increased food production, urbanization, and human appropriation of freshwater have contributed to the loss of wetlands all over the world and threaten the ecological integrity of the remaining wetlands. Major land use and land cover (LULC) changes over the past century of rapid economic development and population growth have contributed to large-scale losses of critical wetlands, with the loss estimated at approximately 50% globally and 54% in the United States (OECD 1996); by 1985, conversion of wetlands to croplands accounted for a global loss of 26% of wetlands (OECD 1996).

Time series of changes in potentially saturated areas, some of which support wetlands, over a 350-year period (1650–1992) were mapped by Steyaert and Knox (2008), illustrating the shifting spatial patterns in the eastern half of the United States. Engineered landscape drainage beginning in 1920 contributed to the large-scale loss of wetlands (see Figure 2). Pressures from the continued need to double food production to meet increasing global demands with population growth, projected to plateau at approximately 10 billion (United Nations 2010), as well as rapid urbanization and growing affluence, are currently converging to threaten the remaining wetlands. For example, in eastern United States, land clearing began in 1600 and steadily escalated until 1920 with drastic LULC changes (e.g., deforestation, land drainage, intensive land use) and once again morphed with some reforestation, urbanization, and intensive agriculture (Steyaert and Knox 2008); these patterns of change reflect the shifting patterns of population and economic growth and also the socioeconomic priorities.

In the past, important ecological services have been traded off to gain socioeconomic services. The consequences of these choices are manifested in impaired water quality, loss of habitats and biodiversity, and other indicators. Draining wetlands has contributed to control of diseases such as malaria, but other adverse public health impacts from wetland loss are more difficult to document (The National Academies 2011). Like other environmental issues, human societies may not be directly impacted, at least in the short term, from loss of aquatic habitats or biodiversity. Yet, long-term cumulative negative impacts of wetland losses and impairment have not been compelling enough to significantly change the trade-offs that societies have made to date. The exceptions are of course the large wetlands, such as the Everglades in Florida.

During the past century, increased understanding and recognition of the importance of wetlands has resulted in significant research efforts and programs to restore wetlands, regulations to prevent loss of remaining wetlands, and construction of new wetlands. Natural wetlands have evolved over geological time scales, and the landscapes dominated by wetlands possess diverse structures as an outcome of self-organization and adaptations and multiple interconnected functions that promote landscape resilience. However, direct and indirect anthropogenic impacts (e.g., LULC changes, climate, and freshwater appropriations) have eroded the resilience of natural wetlands, diminishing their quantity and quality.

Although constructed wetlands intended to replace the losses of natural wetlands are important ecological habitats for a large number of species, the range of services that constructed wetlands provide often encompasses a much narrower spectrum than their natural counterparts. Constructed wetlands have been installed as best management practices in agricultural and urban landscapes to mitigate the export of nutrients and other contaminants to receiving water bodies. However, the efficiency of this function may degrade over time (e.g., due to saturation of nutrient removal capacity) and contribute to even further loss of the original functionality of the landscape. For these reasons, we project a continual decline in the total services provided by wetlands at regional and global scales.

Any type of evaluation of the importance of wetlands must first begin with the recognition that the linkage between human societies and ecosystems varies among rural and urban populations. Urban populations are spatially disconnected from distant wetlands, other than a few constructed wetlands within the metropolitan areas, which serve a limited range of functions. Buffered by technologies, urban communities may not be aware of or may not pay for the consequences of wetland losses or their functional impairment. As such, urbanites may have a cognitive disengagement from the state of wetlands, and they may only be aware of certain functions that immediately benefit them, such as flood mitigation. Therefore, urban social resilience has little dependence on wetlands, except during extreme hydrologic events (e.g., flooding of New Orleans by Hurricane Katrina in 2005).

Rural populations in countries with developing economies are keenly aware of wetland services because they provide key elements of food and water security and cultural values. Loss of wetlands would have direct and immediate impact on such communities, and their socioeconomic resilience is directly and strongly linked to wetland functions and landscape resilience. Rural communities in western societies, and countries with advanced economies, have contributed to the large-scale landscape transformations and have directly benefited from conversion of wetlands to croplands and urban areas. Impairments of water quality and loss of ecological services are manifested at local, regional, and national scales, and yet these communities are not necessarily aware of the direct or indirect impacts of such losses. This is, in part, due to difficulties in economic valuation of ecological services provided by ecosystems, including wetlands (The National Academies 2011).

Here, we consider freshwater wetlands, distributed across landscapes, with physical attributes that vary in time and space at multiple scales depending on hydroclimatic forcing (e.g., rainfall patterns), landscape topography, vegetative cover, and hydrological/ecological connectivity as well as anthropogenic impacts. These variables also determine spatial distribution and organization of wetlands in the landscape and their ecological *connectivity*, expressed as the topological attributes of complex dynamic networks. Furthermore, hydrologic fluctuations, duration of the hydroperiod (i.e., the amount of time that the wetland has standing water over the course of a year), temporal variations in hydrologic connectivity (surface and subsurface), and vegetation dynamics define the habitat quality and play key roles in biogeochemical and ecological processes.

We first provide a brief overview of important wetland characteristics and explore the loss of wetlands over time from a network perspective (see Section 2.11.2). Multiple functions of wetlands and the services they provide are summarized in Section 2.11.3. In Section 2.11.4, we review policies and regulations designed to prevent further losses of wetlands. In Section 2.11.5, we offer guidelines for restoration of natural wetlands and management of constructed wetlands. We base our review on the following key questions:

1. Given the importance of wetlands to the long-term sustainability of food production, ecological services, and flood protection, what are the optimal strategies for restoration of wetlands with these conflicting socioeconomic and ecological goals?
2. What are the current criteria for restoration of wetlands? What criteria should exist to successfully regain lost ecosystem services, either by construction of new wetlands or by restoration of impaired wetlands?

2.11.2 Wetlands as Complex Systems

An all-encompassing definition for something as complex and significant as a wetland is difficult to provide. Scientists are apt to focus on research criteria and classification schemes, while politicians may prefer regulatory standards defined using simpler criteria (Mitsch and Gosselink 2007). Many definitions characterize wetlands based on their hydrology, soils, and vegetation. Wetlands may be grouped into three types: (1) *permanent*, with limited variation in water levels; (2) *seasonal*, with water level fluctuations that are closely linked to seasonal differences in hydroclimatic drivers; and (3) *ephemeral*, with the wetland becoming dry for extended periods during a year. These types of wetlands are intrinsically linked to the hydroclimatic regime in which they are located as well as the size of the wetland and its position within the landscape. A wetland in a humid climate is likely to have lower variability in its hydroperiod, as the timing and amounts of rainfall are less variable in humid and tropical climates as compared to semiarid and arid climates. Therefore, permanent wetlands are likely to be larger wetlands located in humid and tropical climates and positioned in landscapes such that they have large contributing areas. Under these conditions, the amount of surface runoff generated from the contributing drainage area plus the net groundwater flows can sustain the water level in permanent wetlands. Such wetlands are less sensitive to variations in hydroclimatic drivers. Seasonal and ephemeral wetlands are likely to be midsized or smaller wetlands in semiarid and arid climates and are water limited in that the total net radiation energy exceeds the amount of water available for evapotranspiration. In contrast, humid areas are energy limited because the net radiation energy available is less than the volume of water received as precipitation. Thus, smaller wetlands are sustained by runoff from the contributing area, reducing the amount of temporal variability in a wetland's water level. As the types of vegetation and aquatic species that a wetland can support are directly related to the wetland's hydroperiod, classifying a wetland into these three categories is an important first step toward understanding the potential ecological functions that a wetland can sustain.

Several studies have focused on single wetland features, providing an in-depth understanding of the hydrological, biogeochemical, and ecological processes and their interdependencies. For the current discussion, we view wetlands as interconnected nodes in a dynamic complex system, characterized by a web of interdependent internal processes with coupled hydrological, biogeochemical, and ecological consequences. Wetlands are subject to stochastic natural and anthropogenic forcing and have multiple functions that vary over time. In this sense, each wetland might be considered as a complex system in its own right, but we instead examine wetlands as nodes in a network that are distributed across the landscape. Thus, the collective, larger scale functionality and dynamic connectivity of the entire landscape are of interest, especially in terms of the ability to maintain functions under fluctuating conditions, i.e., landscape resilience.

Wetlands in a landscape usually occupy the areas with the lowest elevations. Water levels within wetlands are sustained by runoff from landscape units at higher elevations, from the rise and fall of the local water table or from the stage and discharge dynamics and geomorphology of stream networks. Thus, wetlands (1) serve as hydrologic buffers to mitigate floods; (2) modulate solute loads exported from the landscape through uptake, sequestration, transformations, and retardation; and (3) provide dynamic ecological habitat networks and refuges.

2.11.2.1 Size Distribution

Data compilations (Lehner and Döll 2004; Liu and Schwartz 2011; Zhang et al. 2009) have shown that the wetland area distribution across landscapes tends to follow asymmetrical probability density functions (pdfs). The pdfs of other landscape features, such as lakes, have been shown to follow power law distributions (Downing et al. 2006). An analysis of the wetland sizes in the United States (**Figure 3**) shows that wetland area distribution follows a power law [$p(A) = \alpha A^{-\beta}$], where $p(A)$ is the probability of the occurrence of a wetland of a specific area, A, with α and β being empirical constants.

We note that the area cumulative distribution function (cdf) for different states coalesce surprisingly into only two groups for wetlands greater than 100 m^2. The vast majority of states (>90%) have the same value of β ($=1.1 \pm 0.3$), indicating that the processes controlling wetland formation in these states act in such a way that generates scale-invariant patterns, since a single value of β can be fitted across the entire cdf (**Figure 3**). However, four states (Rhode Island, Delaware, Connecticut, and Hawaii) cannot be characterized by this same value of β, likely due to spatial constraints of small geographic areas of these states. Geographic and landscape constraints limit the largest size of wetlands, while the formal definition of an area delineated as a wetland has a certain minimum size. Thus, the power law pdf may be cutoff, or truncated, on both ends (i.e., smaller and larger wetlands), and other pdf models may be more appropriate (e.g., log-normal, gamma, exponential, etc.). This type of analysis facilitates the multiscale assessment of hydrological, biogeochemical, and ecological processes. In Section 2.11.2.3, we will examine how the area pdfs shift in time with stochastic hydroclimatic forcing.

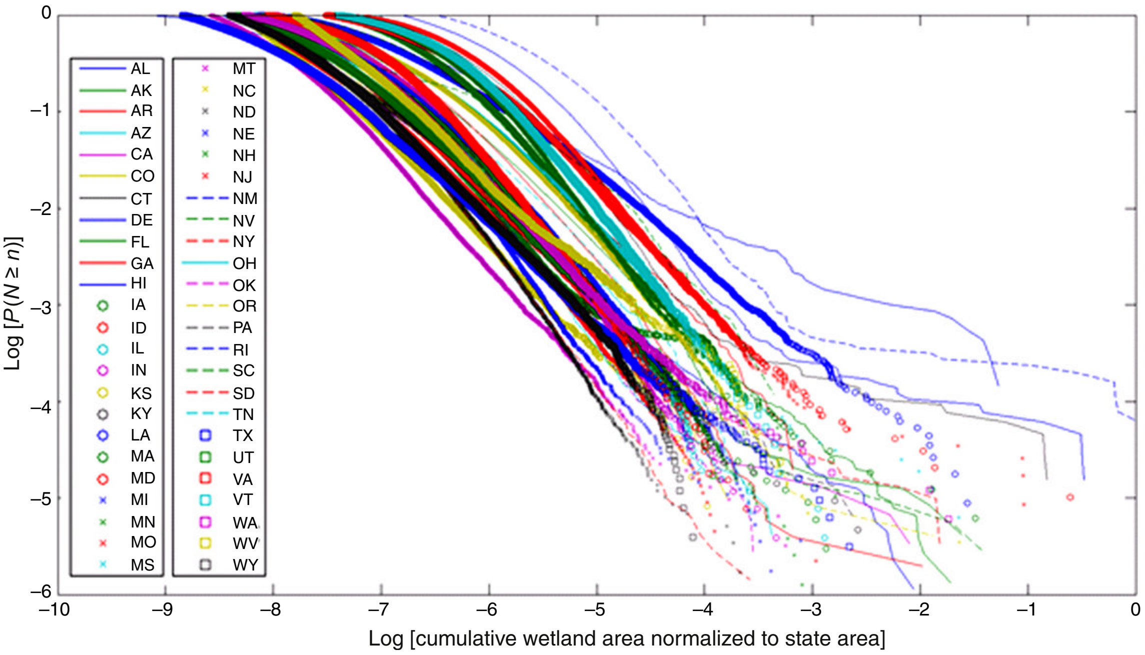

Figure 3 Inverse cumulative distributions of wetland sizes in the United States by state, normalized to the state's area. Data include all wetlands greater than 100 m^2. Data source: USFWS cited 2012: Download Seamless Wetlands Data by State. [Available online at: http://www.fws.gov/wetlands/data/State-Downloads.html.]

2.11.2.2 Wetland Connectivity

Hydrological connectivity of spatially distributed wetlands can occur through (surface) stream networks, through (subsurface) groundwater, or both. Nodes represent individual wetlands, and the hydrological and biogeochemical links are the surface and subsurface water and solute flows between any two nodes. However, we must also consider the ecological links between nodes, which may or may not depend on the hydrologic links, i.e., the dispersal strategies and dispersal ranges of aquatic organisms determine the type of ecological connectivity. Networks can also have directional dependence (e.g., water, solute, and energy flows), in which case they are considered as being *directed* networks. In other cases (e.g., ecological flows), the network flows can be multidirectional. Directed and undirected networks exhibit different abilities to maintain network functions with the loss of nodes and links; thus, landscapes with directed or undirected networks exhibit different degrees of resilience to external perturbations.

Networks are characterized by the distribution of the number of links each node has; this is known as the *node–degree* distribution. The node–degree distribution follows a power law pdf for fractal networks, characterized by scale-invariant network topology. Fractal networks possess 'hub and spoke' geometry, with a few key nodes, or hubs, with a large number of connections, whereas the majority of nodes have a smaller number of connections to other nodes. This would imply that across a landscape, the larger wetlands might serve as hubs to maintain ecological functionality even when the smaller wetlands are lost or the links are disconnected (e.g., during the dry season). Therefore, the loss of the most highly connected wetlands would prove detrimental to the overall ecological functionality of the landscape. Wetland connectivity has been shown to follow a power law pdf, but temporal dynamics of hydroclimatic forcing alter the size and degree of connectedness of the wetland networks, as seen in the changes of the node–degree pdf (Fortuna et al. 2006; Wright 2010).

2.11.2.3 Wetland Dynamics

Natural intra- and interannual variations in hydroclimatic forcing control the wetland area pdf and network connectivity over time. Liu and Schwartz (2011) simulated the century long (1910–2001) temporal dynamics of water-area frequency distributions in the prairie pothole landscapes in North Dakota (**Figure 4**). This time line included the decade (1930–40) of the Great Dust Bowl drought and the more recent (1993–2001) floods, along with strong interannual fluctuations in precipitation. Several features of their simulations are of interest: (1) the area–frequency plots follow power law distributions, which suggest that the wetland distribution across landscapes has fractal (scale-invariant) spatial patterns, albeit with different slopes (i.e., spatial organization and connectivity) for different time periods; (2) starting from the predrought dry conditions in summer of 1928, the area–frequency plot lines shift steadily downward during the Dust Bowl decade as the landscape dries out, but the slopes of the pdfs over time are essentially the same, suggesting that while the total number of wetlands across the landscape was decreasing, their relative frequency distribution remained essentially constant; and (3) starting in 1992 summer before the deluge, the area–frequency plots gradually shifted upward (as the number of wetlands filled with water increases), but with a disproportionate increase in the number of smaller wetlands (increasing slope).

A wetland network with hydrologic connectivity (surface water and/or groundwater) among individual wetlands expands with increasingly wet conditions. But, as the wetlands dry out, the larger wetlands persist, albeit at lower water levels, and provide important ecological refuges during the dry seasons for mobile organisms. This implies that the changes in hydrologic network topology and spatial organization of water area are different during wetting and drying cycles. The outcomes within a wetland network as a result of stochastic hydroclimatic forcing will be nonlinear and path dependent (i.e., wet-to-dry or dry-to-wet), whereas the pattern and connectivity of wetland size distribution are affected by the water storage capacity within the landscape (Shook and Pomeroy 2011).

How does the loss of wetlands and their connectivity impact aquatic habitats and their integrity? Do the smaller more dynamic wetlands play a more important role compared to the larger more persistent wetlands? Species restricted to fixed and islandlike habitat types would be expected to be particularly vulnerable to extinction if their local and regional climate change as the habitat quality and connectivity change or as the current synchronicity between reproductive cycles and the hydroperiod shifts because of altered rainfall patterns. Changes in the spatial distribution of wetland habitats can reduce connectivity among communities and populations (as with habitat loss) or disturb patterns of diversity and adaptation that have developed over evolutionary history (e.g., gene swapping, invasive species). Similarly, rapid changes in the variability experienced by wetlands can have immediate consequences for species diversity and population persistence. The isolated nature of many freshwater wetlands, especially those in human-fragmented landscapes, may mean that many of these species will rely on in situ evolution to cope with the induced habitat changes. Anthropogenic land use changes can occur at short temporal scales (even weeks). Thus, biodiversity changes reflect the dominant role of specialization induced by direct or indirect anthropogenic forcing, whereas selection for plasticity might play an important role over the long term in adapting to climate change.

2.11.2.4 Loss of Resilience: US Case Study

Wetlands, historically viewed as wastelands, were drained in many locations worldwide (Mitsch and Gosselink 2007). As European settlers arrived in the United States, they began to cultivate the land and develop intensive agricultural practices. In time, the largest wetlands were the first to be drained through the installation of major canals and ditch networks. The expansion of croplands and extension of the drainage networks over time lead to the loss of wetland connectivity because of the drainage of increasingly smaller wetlands. These patterns of increased population, industrialization, and prosperity, which in turn drive the need for increased food production and expanded urbanization, have occurred in many countries, contributing to global-scale losses of wetlands over the past century.

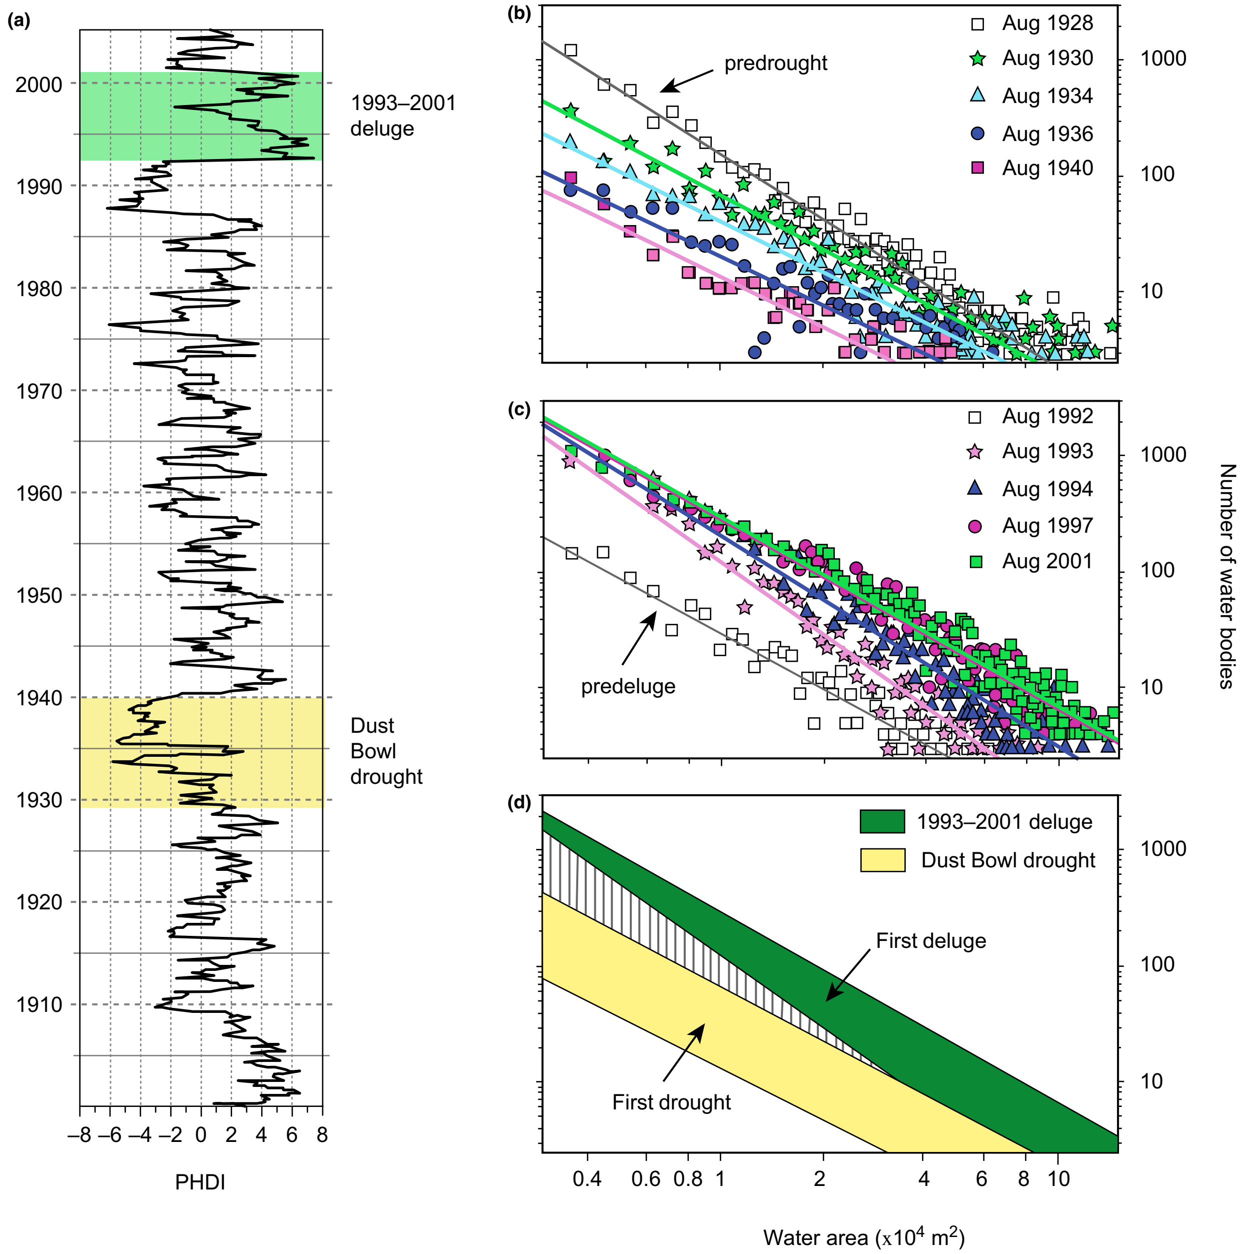

Figure 4 (a) Time series of Palmer hydrological drought index (PHDI) for the Prairie pothole region in North Dakota. Water-area frequency distributions for wetlands during (b) 1930–40 during the Dust Bowl drought and (c) 1993–2001 during the deluge, and (d) summary envelopes showing the variability in wetland size distribution resulting from hydroclimatic extremes. Source: Liu, G. M., and F. W. Schwartz, 2011: An integrated observational and model-based analysis of the hydrologic response of prairie pothole systems to variability in climate. *Water Resour. Res.*, **47**, W02504.

The resilience of fractal wetland networks is highly vulnerable to the loss of keystone wetlands that serve as ecological hubs or as nodes that serve as vital connectors for flows of water, solutes, and energy. Because of the connectedness of wetlands in a larger complex network, the short- and long-term connectivity dynamics have important ecological consequences in terms of species dispersal and persistence. Such consequences result from inter- and intraannual changes in hydroclimatic forcing (e.g., rainfall patterns), aquatic vegetation dynamics, and anthropogenic forcing (e.g., LULC changes).

The spatial organization of wetlands across a landscape also determines the mean distance between wetlands (i.e., the connectivity of patchy habitats). Thus, removing certain wetlands could significantly increase the mean distance between adjacent wetland habitats (as well as the statistical distribution of distances), which would alter the overall functionality and ecological resilience of the landscape. For example, in the Carolina Bays, if all wetlands smaller than 1.2 ha were removed, the average distance between nodes would rise from ∼470 to ∼670 m (Semlitsch 2000). If this increased distance to habitats is larger than the dispersal range of certain aquatic species, their life cycles would be significantly disrupted, leading to the loss of biodiversity.

Wright (2010) assessed the connectivity of a prairie pothole network as the distances between the centroids of wetlands that are equal to or smaller than the dispersal distance of an aquatic organism. That is, if the spatial distance is smaller than the distance that an organism can reach, two wetlands are assumed to be ecologically connected to each other. Therefore, loss of wetlands within a network decreases the probability that the organism can move to an alternative refuge if its current habitat dries out, either due to anthropogenic drainage or due to the duration of the natural hydroperiod. However, not all the wetlands nodes removed cause the same degree of loss for dispersal probability. A node may have a number of neighboring nodes of similar distance, which may act as alternate refuges. If these neighbors are connected, alternate pathways will allow detouring after the node is removed.

Two attributes of wetland networks are important from an ecological perspective: *clustering coefficient* and *centrality*. The property of the connectedness between neighbors is measured as the clustering coefficient or redundancy (Newman 2010). On the other hand, a network node may act as a critical transit point to numerous key species. *Centrality* is a measure of the importance of a specific node in a network; it defines the number of shortest paths that pass through that node, facilitating connections to other nodes in the network (Newman 2010). Removal of a node with high centrality would result in a significant loss of connectivity among network nodes and thus lead to habitat fragmentation, reducing the ability of aquatic plants and organisms to disperse. Therefore, we expect that the loss of nodes with high centrality would contribute to significant loss of certain ecological functions, even though the loss of the associated hydrologic function may be trivial. The removal of critical links leads to the isolation of small clusters from a large network. Gimmi et al. (2011) documented how typical wetland animals with dispersal distances of 0.3–1 km were historically constrained into fragmented habitats and showed that the number of species was reduced by the collapse of a largely connected wetland into medium and small isolated habitats. Such network analysis would provide clear metrics for identifying the gap that the loss of a single wetland leaves in the overall functioning of the landscape and can allow for better planning and design of constructed wetlands or the restoration of degraded wetlands.

2.11.3 Wetlands: Functions and Services

2.11.3.1 Flood Control

Wetlands provide depression storage for surface water and thus regulate the precipitation excess that contributes to runoff and recharge. Vegetation also increases surface roughness and as such serves an important role in slowing the rate of water flow across the landscape during flood events (Williams et al. 2012). Thus, removal of numerous wetlands within a landscape will result in loss of surface storage and increased runoff, while groundwater recharge rates and water quality decrease (Plocher and Levin 2003). This emphasizes the fact that even small wetlands play a significant role within the larger context of flood prevention utility provided by the wetland network.

Changes in flood patterns can be particularly damaging to urban communities (increased flood risk) and to wildlife that depend on stable hydroperiods. A shift from flood-dominated wetlands to a drained landscape also presents problems for native species, as the altered system may be better suited to invasive species (Pringle 2001). Loss of riparian wetlands and conversion of landscapes for intensively managed croplands and urban areas have contributed to increased intensity and frequency of floods in the Mississippi River Basin (Olson and Morton 2012). These examples exemplify the role that wetlands play in protecting ecosystems and urban settings, which become increasingly vulnerable to extreme hydroclimatic events when wetlands are lost. With the possibility of changes in frequencies of floods and droughts, the loss of wetlands only exacerbates the adverse impacts experienced by human communities and aquatic species that depend on wetland functions.

2.11.3.2 Biogeochemical Filtering

Wetlands act as filters for water quality improvement by reducing the export of sediments, nutrients, and other contaminants to downstream aquatic ecosystems. The loss of wetlands represents a loss in the buffering capacity of the landscape to mitigate anthropogenic impacts, and directly contributes to increases of solute loads exported from the landscape, impaired water quality, and reduced habitat integrity. The effects of wetland loss are particularly evident in the corn–soybean belt in the Midwest United States. The conversion of a mosaic of erstwhile prairies, forests, and wetlands to monoculture croplands and intensive animal production (e.g., concentrated animal feeding operations) has contributed to dramatic increases in exported loads of nutrients (N and P), pesticides, pathogens, and other contaminants (e.g., hormones, veterinary pharmaceuticals) to receiving water bodies. The impacts of intensive agriculture have affected aquatic ecosystems at all scales, with the persistent, large-scale coastal hypoxia in the Gulf of Mexico one of the most notable impacts (Diaz and Rosenberg 2008; Kemp et al. 2009; Rabalais et al. 1996, 2002; Smith et al. 1999). Similar hypoxia is noted in many other coastal waters all over the world. The World Resources Institute has identified 415 locations around the world as experiencing eutrophication to some degree, 169 of which are hypoxic (Selman et al. 2008). Such widespread examples of water quality degradation show that the removal of wetlands causes significant unintended consequences for downstream ecosystems through the alteration of hydrological and biogeochemical cycles.

2.11.3.3 Ecological Habitats

Ecological functionality of wetlands networks are largely driven by complex interactions among external forcing (natural and anthropogenic) on the landscape features, hydrologic dynamics within and among nodes, biogeochemical efficiency in nutrient processing, and the ecological responses of resident populations and species. Both short- and long-term changes in hydrologic connectivity, habitat quality and integrity, and the spatial distribution of wetlands within the landscape can result from acute and chronic shifts in external forcing and internal feedbacks. The persistence of biodiversity and resilience of wetland communities are impacted by the interdependence of forcing and hydrologic and biogeochemical responses of landscapes. Thus, two dominant attributes of wetlands as ecological habitats are relevant to our considerations here: structure (form) and ecological services (functions). In particular, the hydroperiod (intraannual variability) and the vegetation composition are key features that determine the habitat suitability and integrity. High-temporal variability in structure is essential in some cases for the persistence of certain species, while temporal stability of structure is needed for the persistence of other species. Thus, the hydroperiod plays a key role in the maintenance of habitat and species diversity.

Wetlands provide a highly structured, nested spatial context that shapes the composition of resident communities and the evolutionary trajectories of the organisms that inhabit them. This spatial structure influences the distribution and abundance of organisms at multiple scales, ranging from the organization of wetland features across a landscape to the distribution of microhabitats within individual wetlands. The association between organisms and specific ecological conditions generates high levels of community and population structuring within patchy habitats, and the extent of 'connectedness' among suitable habitats has fundamental implications for the distribution and maintenance of species diversity (MacArthur and Wilson 1967) and population persistence (Hanski 1999; Levins 1970).

Wetlands are not only structured and connected habitats for a broad range of organisms, but can also serve as population sources and sinks or stepping stones for dispersing individuals. Small and isolated wetlands have the largest potential to serve as stepping stones in a wetland network, allowing connections to more distant wetlands in otherwise fragmented smaller wetland clusters. Without such nodes, both the density and types of individuals migrating will diminish as dispersal distances become too great for some species (Semlitsch 2000). This can create wildlife population sinks: isolated locations where mobile species take refuge when most or all other options are unavailable. Such areas are created when too much habitat is lost and/or connectivity to other habitats is destroyed. Refugee species persist in the remaining viable habitat(s), living on what resources are available within the sink. Initially, the collection of refugee species leads to a population boom (Pringle 2001). However, these sinks are detrimental to the local ecosystem, as refugee species put a strain on local species and consume resources. Once the sink location is exploited of resources beyond its carrying capacity, the refugee species will endure a subsequent population bust (Pringle 2001).

2.11.3.4 Economic Benefits of Wetland Services

Wetlands worldwide are frequently drained to create suitable cropland and urban settlements with tightly managed hydrological regimes and ecological properties. The immediate socioeconomic benefits of increased land area for food production often outweigh the hydrological, biogeochemical, and ecological benefits that can be obtained from wetlands. Significant benefits provided by wetlands are usually overlooked, including their key direct and indirect contributions to food and water security. Direct uses of wetlands for food include protein sources such as fish, grain sources such as rice paddies and fodder for farm animals, as well as a source of drinking water. It is estimated that rice paddies feed half of the world's population, a highly significant source of nutrition that otherwise cannot be met. Many cultures utilize wetlands as sole protein sources, as isolated wetlands may provide the only hospitable habitat for fish and other animals (Abbot and Hailu 2001).

In countries with high intraannual precipitation variability, wetlands provide bursts of food services that can be used to maintain yearly food security. For example, corn and other vegetables are often cultivated using water from wetlands in countries with high intraannual precipitation variation. The rainy season provides precipitation necessary to facilitate crop growth. Food becomes ready for harvest once the dry period begins providing essential food products that can sustain the population through the dry season. Such wetlands also serve as essential sources of drinking water, especially when water levels are sustained throughout the year (i.e., hydroperiods are long) (Abbot and Hailu 2001).

As wetlands are continually drained to create efficient large-scale agriculture and urban settlements, numerous beneficial services are lost. Nutrients and pesticides applied to intensively managed croplands or urban areas (i.e., lawns) are transported to nearby receiving water bodies during storm events, impairing groundwater and surface water quality. Herbicides, such as atrazine, can have long-term ecological health effects, especially for sensitive aquatic species, and increase the need for water purification to protect public health. Sensitive aquatic species (i.e., fish) can be adversely affected in watersheds that are impacted by intensive agricultural practices (Durhan et al. 2006; Leet et al. 2011; Smith et al. 1999; Soto et al. 2004), sometimes leading to localized and regional species population collapse and unforeseen food web alterations. As such, wetland ecosystems unable to endure perturbations can become damaged irrevocably, potentially leading to decreased availability of protein sources (such as fish) and loss of other components of the food web.

In some cases, services once provided by a wetland may never be fully recovered. The loss of vital protein sources as well as water filtering and nutrient processing are perhaps the most dramatic causes of degraded food and water security. As monoculture crops are unsustainable in the long run due to the corresponding loss of landscape resilience, it is important to preserve as many natural wetlands as possible. Removing nodes especially based on size and location without knowledge of connectedness to the network will lead to continual ecosystem degradation and species collapse.

Indirect contributions to food and water security come in the form of economic advancement. As with the harvesting of corn and other vegetables, many localized crafts are dependent on wetlands, particularly in rural communities. Baskets may be fashioned from reeds and sold in order to make money, which can be used toward the purchase of food. Farm animals graze on wetland vegetation and thus serve as both a direct source of protein and an indirect source of food through meat and dairy sales. Even medicinal plants are harvested and sold (Abbot and Hailu 2001). Because of the various ways in which wetlands contribute to food security and economic well-being, organizations are calling for effective management of wetlands in order to sustain and expand the role wetlands play.

Ecotourism, rising in popularity, is another indirect link to food and economic security. As wetlands grow in popularity as places to learn and relax, revenue generated by tourism can be used toward economic stability and food security. A positive facet of ecotourism is that revenue is generated without the extraction of resources from the wetlands. On the other hand, too much tourist traffic can lead to overall degradation of the wetland in terms of ecological benefits, viable habitat space, water quality, and scenic value (Mitsch and Gosselink 2007).

2.11.4 Policies to Prevent Wetland Losses: US Case Study

The initial political recognition of wetland degradation in the United States occurred in 1977 when Executive Order 11990 was signed, which sought to encourage agencies to minimize their negative impacts on wetlands. Twelve years later, the No Net Loss of Wetlands policy was endorsed (Turner et al. 2001). In addition, Section 404 of the Clean Water Act that contains provisions for wetland mitigation was updated in 2008. The goal of the No Net Loss policy was to replace or restore an equivalent spatial area of wetland for every wetland lost due to alteration or destruction. Different types and sizes of wetlands serve unique roles in the larger landscape. With the No Net Loss policy, there are no formal guidelines stating the proportion of wetland sizes to be replaced; the Environmental Protection Agency (EPA) generally follows a 1 ha destroyed to 1 ha created metric. In practice, this allows the creation of a single large wetland to replace multiple smaller wetlands, as long as the total area replaced is equivalent to or greater than the destroyed area.

Wetland replacement on a one-to-one area basis is not ecologically or hydrologically equivalent, when several small wetlands are replaced by one large wetland. In particular, Turner et al. (2001) found that among four states surveyed, only about 70% of the total destroyed wetland area had been recovered or replaced. This does not account for functional replacement, which is typically only about 20% of original wetland losses. Vegetation cover is generally the largest metric used to determine wetland health. This metric alone does not begin to address many key functions of wetlands, thus causing the reduction in realized functional recovery (Windham et al. 2004).

According to the US Department of Agriculture, the No Net Loss policy has been quite effective, with approximately 250 000 acres of forested wetlands developed between 1998 and 2004 (Dahl 2006). This acreage is larger than the total wetland acres lost during that time period, thus allowing the National Resource Conservation Services (NRCS) to deem the No Net Loss policy successful. Although this claim of success is true for recent times (i.e., since 1998) on an area basis, it ignores the effects of size, location, and distribution of wetlands on overall wetland services and ecosystem health. Furthermore, large-scale losses prior to the enactment of this policy are not addressed in this positive assessment.

The EPA and Army Corps of Engineers created the National Wetlands Mitigation Action Plan in 2002, which outlined the methods of compensatory mitigation for wetland replacement and creation, stating that restoration, establishment, enhancement, and preservation are all vital elements of wetland policy. Gains in wetland functions are desired but not necessary to meet permit requirements. Mitigation types are not recorded by the US Army Corps permitting districts, making functional restoration difficult to evaluate (Wilkinson and Thompson 2006). Furthermore, permits issued for wetland reclamation and creation can go uncompleted or fail to be issued, and the timelines for efficacy assessment typically do not extend 5 years (Turner et al. 2001; Windham et al. 2004). Adequate placement, extended monitoring metrics and timelines, and standard permit enforcement would be a start toward solving the problem of ineffective and inadequate restoration and recreation of wetlands. In addition, food and water security and long-term landscape resilience must be added to the discussion, enabling policy leaders to understand the functions and roles of wetlands in society (Oneka 1999).

Policies and practices that lead to losses of wetlands during the past century were based on a lack of understanding of the interconnectedness of the landscape elements and coupling among landscape processes in maintaining landscape functions and overall resilience. Incremental changes at the local or regional scales were presumed not to be cumulative in time and failed to acknowledge that local impacts can propagate and amplify over spatial and temporal scales. Furthermore, the adverse outcomes of persistent and continually intensifying stresses on landscapes at regional and global scales were not fully appreciated until recently.

The fragmented nature of policies and regulations, often overlapping and sometimes contradictory, uncoordinated landscape management by multiple federal and state agencies, and scientific explorations disconnected because of disciplinary boundaries have all contributed to the continued degradation of wetland ecosystems from increasing anthropogenic stressors. An interdisciplinary approach to scientific investigations and an integrated systems approach to management are becoming increasingly common. Two essential features of the new paradigm are (1) considering the landscapes as coupled complex systems, such that essential features of form (size distribution, location, patchiness, connectivity) and critical functions are retained to maintain landscape resilience and (2) adaptive management that relies not on rigid plans, but incorporates flexibility and learning from sufficiently large restoration efforts to reduce uncertainties and adverse unanticipated outcomes.

2.11.5 Paths to Wetland Restoration

2.11.5.1 Managing for Resilience

Modern industrial agriculture is based on maximizing economic returns through increased crop yields and attempts to minimize risks of crop losses. Thus, land management practices are predominantly driven by increased efficiency and risk avoidance, just the same as other engineered industrial systems such as manufacturing. This pursuit of efficiency in agricultural landscapes has contributed to the loss of natural diversity and heterogeneity within the landscapes, causing functional homogeneity to emerge (Basu et al. 2010). Risk avoidance and efficiency maximization management strategies may increase the stability and predictability of complex systems, but decreased diversity and adaptive capacity make such engineered systems more vulnerable to unforeseen 'shocks' from external drivers. Park et al. (2012) proposed an improved management strategy – based on a blending of risk- and resilience-based approaches – for engineered complex systems, which is also suitable for landscapes dominated by wetlands.

The unintended consequences of engineering of landscapes are that (1) increased drainage efficiency (due to loss of wetlands and their water retention capacity) leads to flashier flow patterns, increased flood risk, and degradation of aquatic habitats; (2) hydrologic responses of agricultural catchments are dominantly controlled by hydroclimatic forcing because the spatial variations in soil–water deficits (created by evapotranspiration losses) are homogenized by monoculture crops; and (3) long-term, repeated fertilization contributes to the build-up of excess nutrient stores within soils and homogenizes the biogeochemical responses such that nutrient loads exported to receiving water bodies are controlled by discharge patterns. Each of these characteristics of an industrialized agricultural system managed for efficiency have significant implications for sensitive aquatic ecosystems, which are now much more vulnerable to shifts in hydroclimatic forcing.

Given the vulnerability of wetlands and the communities that depend on them for survival, landscapes need to be managed from a resilience perspective rather than from an efficiency perspective. Managing for efficiency has caused the loss of the natural resilience of landscapes, and therefore the potential for collapse of ecosystem structure and function is increased under some climate change scenarios. Efficiency-based crop production or urbanization must be traded for landscape management based on improved resilience. Two key features to restore are (1) structural and functional diversity, which in turn enhances the adaptive capacity of a system when confronted with low-probability high-consequence disturbances (e.g., droughts, floods) and (2) adaptive management, in which managers are flexible and able to cope with system diversity (e.g., diverse crops rather than monoculture cropping, with diverse management practices). That is, landscape management should not be optimized based on achieving the highest efficiency and stability; instead, the goal should be to optimize for sufficient diversity, variability, and adaptability for greater landscape resilience. However, managing for landscape resilience under the uncertainties of future climate is a major challenge. Strategies that aim to increase diversity (thus, enhance adaptability) are desirable but may not be sufficient; the Modern Portfolio Theory (MPT) can be used to optimize spatial allocation of resources either to achieve maximum conservation benefits for a unit of monetary investment for a given level of uncertainty or to minimize uncertainty given an expected level of conservation benefits (Ando and Mallory 2012).

2.11.5.2 Restoration Suggestions

Wetland restoration should start with an integrative approach. Understanding the underlying fundamental connections between hydrological, ecological, and biogeochemical factors greatly increases the chance for success of created and restored wetlands. Seeing wetlands as nodes in a complex network across a landscape enables scientists, land managers, and policy makers to better understand the consequences of wetland removal in addition to better monitoring the success of policies such as the No Net Loss policy. Wetland preservation must extend beyond the typical isolated location of importance (Amezaga et al. 2002). Both the size of a wetland and its location within the wetland network play a role in its ecological significance (Semlitsch 2000). Urban or constructed and natural wetlands possess different attributes because they are subject to differing climatic and physical alterations (Windham et al. 2004). As such, metrics for wetland restoration success should include distinctions for spatial organization, connectivity, and hydrologic regimes to further enable proper maintenance and care.

Urban wetlands produce a limited species pool, and thus generalized species cover is not a good indicator of ecosystem functioning for such wetlands (Windham et al. 2004). Hydrological and ecological connectivities have an important role in predicting wetland species richness and as such, should be a major component in policy formation and wetland restoration efforts. Placement among existing natural or constructed corridors (e.g., forest, meadow, etc.) is another key determinant of reaching the desired overall ecosystem health and species representation (Brown et al. 2012). While restoration of wetland hydroperiods is essential, improving habitat quality and connectivity to sustain species diversity is more important. Therefore, targeting restoration efforts to maximize the desired ecological, hydrological, and biogeochemical effects is perhaps the best solution to ensure successful implementation of policies such as the No Net Loss policy.

Because the large extent of damaged and modified wetlands has already passed tipping points, after which the restoration may be only partially revocable, it might be unrealistic to picture a restored landscape that fully serves ecologically favored functions in a short time frame. Moreover, changes in LULC surrounding wetlands will limit the full recovery of an altered landscape. These changes should be maintained at some levels to provide critical socioeconomic services. As there were once critical links that connected the now isolated clusters of wetlands, identifying the critical pathways that hydrologically and biologically reconnect these clusters will be an effective way for restoring a landscape.

2.11.5.3 Guidelines for Constructed Wetlands

Power law distributions, which emerge and are observed in numerous natural systems, indicate the ability of a system to self-organize when constantly pushed to a disordered state by natural perturbations (Barabási 2003). Also, the power law patterns are indicative of optimum diversity, which is critical for resilience. Anthropogenic forcing has modified wetland networks through removing nodes (wetlands) and links (connectivity among wetlands), resulting in a narrower range in variation of wetland sizes and connectivity.

Humans have changed wetland networks toward a state of decreased diversity and increased isolation. While bounded variation may serve efficient management for human purposes, the built-in rigidity will eventually lead to the systematic failure of hydrological, ecological, and biogeochemical functions that are maintained by self-organization and adaptation through the connectivity of wetlands. Thus, the construction and/or restoration of wetlands should strategically aim for allowing self-organization for the system as a whole and reducing the physical constraints (e.g., roads and settlements) that restrict ecological connectivity.

Understanding the interdependence and synchronicity of hydrological, biogeochemical, and ecological functions helps current efforts to mitigate the impacts on water quality and habitat suitability. An increased understanding of the role wetlands play in the overall ecosystem services provided by natural wetlands would present a unique opportunity to implement new standards for the design and implementation of constructed wetlands as best management practices, taking size, persistence, and connectivity into account. The resilience of wetlands is a function of hydrological, biogeochemical, and ecological connectivities clustering coefficient, centrality measures, and the role that wetlands of different sizes play in the overall functionality of the landscape.

As societies continue to seek socioeconomic progress, landscape efficiency is generally achieved at the expense of landscape resilience. However, socioeconomic progress and landscape resilience could be achieved simultaneously if vital wetlands within the landscape are protected and/or efforts are focused on understanding, quantifying, and restoring the functions of landscapes that had previously been sacrificed for socioeconomic gains. Constructed wetlands must be designed to optimize the various functions such that the original function of the landscape can be restored. The location of the constructed wetlands should be seen as an important design aspect to enable the constructed wetlands to play an important role in the connectivity of the overall landscape. Wetlands have the potential to serve important functions for increasing ecological and hydrological connectivities and the design and implementation of constructed wetlands should optimize these potential benefits beyond best management practices for nutrient removal. We envision that constructed wetlands could then be spatially targeted to maximize these beneficial functions while maintaining food security for generations to come.

2.11.6 Summary

Wetlands have evolved over millennia as self-organized and resilient elements of a landscape, which has been shaped by hydrologic and geologic forces. Stochastic hydroclimatic forcing strongly controls the spatial self-organization and connectivity of wetlands, and the temporal dynamics of the interdependent functions of the complex wetland networks. Aquatic species that depend on mosaic of wetlands as patchy habitats have also adapted their life cycles to the spatial organization and temporal fluctuations of the dynamic wetland networks. Rural populations, particularly in developing countries, continue to depend on the many services provided by freshwater wetlands, including food supply and drinking water. Persistent and increasingly dominant anthropogenic impacts – including increasing population, economic growth, freshwater appropriations, urbanization, and other direct and indirect impacts – have contributed to loss of about half of the freshwater wetlands worldwide, degradation of the remaining wetlands (OECD 1996), and loss of biodiversity through fragmented, isolated, and degraded aquatic habitats.

In urban communities, the loss of wetlands and the associated trading of ecological services for short-term socioeconomic benefits have enhanced food, water, and economic security and contributed to improvements in public health. However, such gains have undermined the ecological resilience of natural landscapes, and in the long term, will constrain the continual unsustainable practices in land and water management. Thus, urban food and water security in the long term are threatened by wetland degradation and removal. In developing countries, persistent connections to, and dominant dependence on, landscapes for provision of a mix of socioeconomic, cultural, and ecological services has reduced the socioeconomic resilience of the rural communities.

Restoration of degraded wetlands, as well as design and management of constructed wetlands, must recognize the importance of spatial organization, connectivity, and interdependence of wetland internal processes and functions. Thus, optimization for trade-offs among socioeconomic and ecological services without the loss of overall landscape and social resilience is essential for the long-term sustainability of food, water, and socioeconomic security.

2.12.1 Introduction

The impacts of climate are evident on temperature and precipitation. For instance, global and regional land surface temperatures increased in the twentieth century, with the greatest warming in the last three decades (WMO 2005). The diurnal temperature range is narrowing in many regions across the world owing to the differential changes between daily maximum and minimum temperatures (Easterling et al. 1997). Significant changes have also been noted in climate variables (i.e., precipitation and air temperature) across the United States. Trends in observed precipitation suggest an increase in number of days with extreme precipitation during the twentieth century (Kunkel et al. 1999). An increase in mean air temperature was also reported (Karl et al. 1996). At the regional scale, Mishra et al. (2010) and Charusombat and Niyogi (2011) reported that precipitation, daily minimum air temperature, soil moisture, and runoff increased over the twentieth century, whereas daily maximum air temperature, ice content of the soil, and snow water equivalent experienced decline in Indiana and Illinois, and is expected to be a pattern that is true for the broader Corn Belt. Fall et al. (2011) and Martinez et al. (2012), however, show that the interpretation of trends in maximum and minimum temperatures is complicated by station sitting quality. As shown in Fall et al., poorly sited locations had an overestimate of minimum temperature trends and an underestimate of maximum temperature trends.

Some of these trends in climate variables (e.g., precipitation and air temperature) might persist under the future climate (Easterling et al. 2000; Sheffield and Wood 2007; Diffenbaugh et al. 2008; Diffenbaugh and Ashfaq 2010). Hayhoe et al. (2007) hypothesized an increase in annual air temperatures and changes in precipitation patterns in the future. However, although these projections provide a subset of plausible future regional climate, they do not cover all of the possible climate threats in the coming decades. This is why the bottom-up focus is needed with respect to climate risk.

For example, decreases in precipitation and increases in daily maximum air temperature in the coming decades could lead to persistent water stress conditions that could hamper crop production in the US Corn Belt. An occurrence of drought during the crop growing season often affects plant growth, crop yields, and in turn, food production. Increases in temperature and heat waves, as well as decreases in precipitation and snow storage, would further enhance the likelihood of drought occurrences. Globally, the impacts of drought and climate on crop yield and food production have been well documented in previous studies (Lobell and Asner 2003; Lobell and Field 2007; Mishra and Cherkauer 2010). Statistical as well as physics-based crop models predict that grain yield declines by 2.5–16% for every increase of 1 °C in seasonal temperature in the subtropics and tropics (Lobell et al. 2008; Battisti et al. 2009). Moreover, Schlenker and Roberts (2009) demonstrated nonlinear impacts of temperature on crop yields in the United States, showing that crop yields decline sharply when temperatures rise above 32 °C.

Historic drought events have had an observable impact on crop yield in the United States. Drought and heat waves caused about $145 billion damages to crop production across the United States (Lott and Ross 2006) during the last three decades. A 30% reduction in US corn production resulted from the drought of 1988 (Rosenzweig et al. 2001) and accounted for a loss of about $39 billion (Easterling et al. 2000). The US Corn Belt produces about 41% of world's corn and about 38% of world's soybeans (Schlenker and Roberts 2009), and is a major contributor of food aid to the African nations through the USAID program. The impacts of future climate, including interannual/decadal variability on US grain production, can contribute greatly to the uncertainty of future food production as well as to the efforts that are being undertaken to make the world more food secure. Climatic extremes such as droughts, floods, heat waves, and abnormally cold temperatures during the crop growing season undermine productivity and, in turn, crop yields (Funk et al. 2008; Lobell and Burke 2008; Battisti et al. 2009). This chapter provides a long-term (1915–2009)

http://dx.doi.org/10.1016/B978-0-12-384703-4.00223-9

analysis of different climatic vulnerabilities such as drought, heat waves, and growing degree-days that might influence corn and soybean production in the US Corn Belt.

2.12.2 Methods

The author evaluated historic climate and its impact on corn and soybean yields in the US Corn Belt. The study domain is identified as the states that largely contribute to the production of corn and soybean as described in the National Agricultural Statistics Service (NASS 2009) (crop yield and plantation) data. This resulted in the selection of 13 states: Illinois, Indiana, Iowa, Kansas, Kentucky, Michigan, Minnesota, Missouri, Nebraska, North Dakota, Ohio, South Dakota, and Wisconsin.

Daily climate data, including maximum and minimum temperatures and precipitation, were obtained from the National Climatic Data Center (NCDC) for the period 1915–2009. The daily station data for the climate variables were then gridded (one-eighth degree spatial footprint) to remove spatial and temporal inconsistencies using the methodology presented in Hamlet and Lettenmaier (2005). To assess the impact of drought and heat spells on crop production in the US Corn Belt, the focus is on the reproduction and grain-filling period of corn and soybean crops (June–August, JJA), because this is the most sensitive period to climate extremes that adversely impact yields (Mishra and Cherkauer 2010). The author selected precipitation, maximum temperature (TMAX), minimum temperature (TMIN), standardized precipitation evapotranspiration index (SPEI) (Vicente-Serrano et al. 2010), and cumulative heat index (CUM_HEAT) for the grain-filling season to evaluate the impact of drought and heat spells on the crop yields in the Midwestern United States. Moreover, growing degree-days (GDD) were estimated for the entire growing season. The growing season for corn and soybean crops was estimated based on the start of the growing season (GSS) and the end of the growing season (GSE). To represent the impacts of extreme warm temperature, the CUM_HEAT was estimated for the grain-filling period during the crop growing season. The CUM_HEAT was estimated for each year as the cumulative temperature (sum of $\mathrm{TMAX_{day}}$–TMAX at 90th percentile) when daily maximum temperature exceeds the 90th percentile of the reference temperature (1961–1990). The SPEI was used to estimate droughts in the grain-filling season. The SPEI is similar to the standardized precipitation index (SPI); however, it accounts for the moisture deficit that could arise from evapotranspiration losses. Monthly SPEI was estimated between 1915 and 2009 for the grain-filling season. For this, a 3-month SPEI at the end of August (representing cumulative moisture conditions for the JJA period) was found suitable for the grain-filling period. Severe (SPEI: −1.3 to −1.5), extreme (SPEI: −1.6 to −1.9), and exceptional droughts (SPEI less than −2.0) can hamper the crop growth and yields.

The GSS and GSE dates for the corn and soybean crops were estimated following Qian et al. (2010). The GSS was defined as the day when the weighted mean air temperature has reached the minimum cardinal temperature ($\mathrm{CT_{min}}$, 10 °C, for corn and soybean crops) and remained above this temperature for five consecutive days. The GSE was estimated when the weighted mean air temperature reached $\mathrm{CT_{min}}$ (10 °C) and stayed below $\mathrm{CT_{min}}$ for five consecutive days. The weighted mean air temperature for each day was estimated using 5-day binomial smoothing. The GDD were estimated by summing daily mean temperature values above $\mathrm{CT_{min}}$ (10 °C) from GSS to GSE using the following equation:

$$\begin{aligned}&\mathrm{GDD} = \frac{T_{\max} + T_{\min}}{2} - \mathrm{CT_{min}},\ \text{and}\\&\mathrm{GDD} = 0\\&\text{if}\\&\frac{T_{\max} + T_{\min}}{2} < \mathrm{CT_{min}}\end{aligned} \tag{1}$$

Wavelet analysis was used to understand the temporal variability of the selected climatic indices. Wavelet analysis provides time variance of signal of any given time series of climate data (Torrence and Webster 1999). Wavelet analysis has been widely used and has become a tool for analyzing localized variation of power within time series (Torrence and Compo 1998). For the analysis, the Morlet wavelet was used (Torrence and Compo 1998; Torrence and Webster 1999). The wavelet power spectrum gives a measure of time series variance at each period and scale (e.g., 2–5 year) and each time (e.g., 1950–90).

The nonparametric Mann-Kendall trend analysis and composite analysis was adopted to evaluate long-term (1915–2009) climate variability. Mann-Kendall trend analysis is a nonparametric test; therefore, it does not rely on normality of the dataset. The composite analysis for extreme 5 years was used to identify the spatial variability associated with extremes of the selected indices. The first difference method was used (Lobell and Field 2007) for both crop yield and climate index to evaluate the relationship among them. The first difference method helps eliminate the effect of technology and other management-related factors on crop yields. The yield of any given year was subtracted from the next year and the difference was considered a contribution from climate variability. The first difference time series were regressed to understand the amount of the variability in the crop yield explained by the particular climate index. Regression analysis was performed between domain averaged crop yields and climate variables.

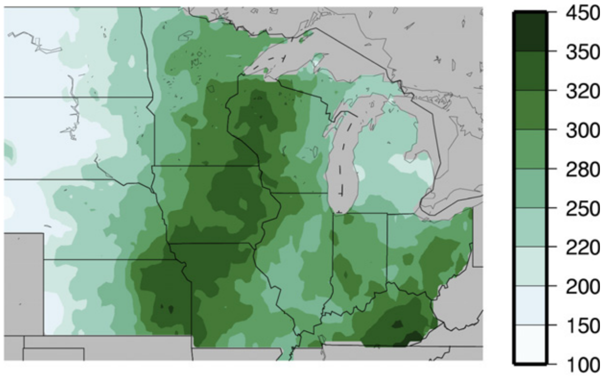
2.12.3 Results

2.12.3.1 Mean Climate during the Grain-Filling Season

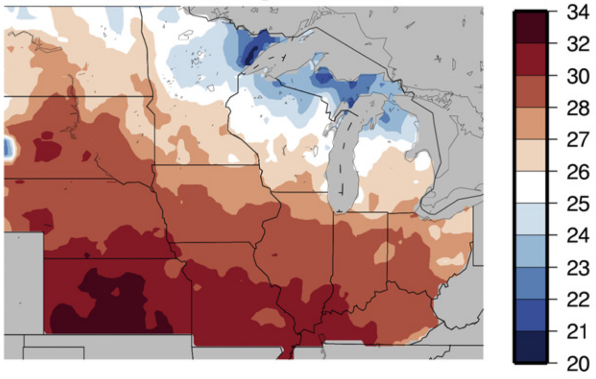
Figure 1 shows mean annual precipitation and maximum and minimum air temperatures for the entire Corn Belt during the long-term (1915–2009) retrospective period. During the grain-filling season (JJA), mean annual precipitation varied from 100 to 450 mm (Figure 1(a)). Mean annual precipitation is somewhat lower in the western part of the Corn Belt, whereas the central part receives higher precipitation during this season. Strong variability exists in mean annual maximum temperature along the north–south gradient of the Corn Belt (Figure 1(b)). For instance, mean annual maximum temperature is about 20 °C in the northern part of the domain, whereas it reaches up to 34 °C in some parts of the southern Corn Belt. Mean annual minimum temperature during the grain-filling season varies from 8 to 20 °C from north to south (**Figure 1(c)**). Results indicate that during the grain-filling season mean annual air temperature is higher than the 13 °C across the Corn Belt.

Temporal variability in mean annual precipitation, maximum and minimum air temperatures for the period 1915–2009 is presented in **Figure 2**. The domain average response of precipitation suggests that the Corn Belt region experienced some prolonged dry spells during 1930–36, 1970–76, and 1980–90 (**Figure 2(a)**). On the other hand, only a few above normal (precipitation anomaly >60 mm) events were found in the entire record of 95 years. The exceptional high precipitation event that occurred in 1993 caused significant flooding during the grain-filling season in the US Corn Belt. The long-term precipitation record suggests that mean annual precipitation for the grain-filling season has increased significantly (slope = 2.8 mm per decade, $p < .05$) during the period 1915–2009. Covariability of droughts and abnormally high air temperature is also evident from the long-term record (**Figure 2(b) and 2(c)**). For instance, during the two historic drought periods (1930s and 1988), the mean maximum and minimum temperature were higher than normal by about 2 and 1 °C, respectively. Dry conditions with hot spells pose detrimental impacts on crops as soil moisture depletes faster with high evapotranspiration loss in these conditions. Long-term trends suggest increases in minimum temperature with slight decline in maximum temperature during the grain-filling season. The Corn Belt region has experienced a significant increase in annual minimum temperature (slope = 0.07 °C per decade, $p < .05$); however, the trends in maximum temperature (slope = –0.06 °C per decade, $p > .05$) are not significant (**Figure 2(b) and 2(c)**).

(a) Precipitation (mm)



(b) Maximum Temperature (°C)



(c) Minimum Temperature (°C)

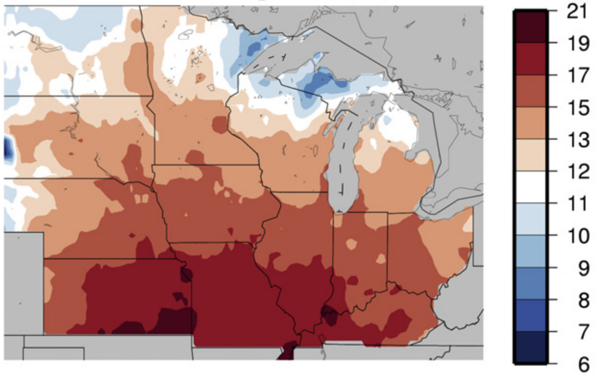


Figure 1 Mean annual precipitation, maximum and minimum temperatures for the grain-filling period (JJA) between 1915 and 2009.

Figure 3 shows spatial patterns of trends in precipitation and maximum and minimum temperatures during 1915–2009. Mean annual precipitation in the grain-filling season increased substantially (up to 14 mm per decade) in some parts of the Corn Belt (**Figure 3(a)**). Increases in mean annual precipitation are evident in the southern parts of Michigan, Wisconsin, and Minnesota and in the northern parts of Indiana, Illinois, and Iowa. Some areas within the Corn Belt also show a decline in precipitation; however, these reductions were not statistically significant. In general, for the US Corn Belt, an increase in precipitation favors crop growth and yields and provides sufficient moisture for a longer duration (depending on soil and other meteorologic conditions) that can satisfy the evapotranspiration demands of corn and soybean. Maximum temperatures have reduced by 0.10–0.30 °C per decade between 1915 and 2009 during the grain-filling season (**Figure 3(b)**). The reduction in maximum temperature is particularly evident in the central domain of the Corn Belt, and parts of this overlapped with the regions with increased precipitation (**Figure 3(a)**). Therefore, part of this cooling might be attributable to the increased cloud cover and evaporation from soils and transpiration from the vegetation in the region. On the other hand, the Corn Belt region has experienced somewhat consistent increases in mean annual minimum temperature during the grain-filling season (0.10–0.30 °C per decade) (**Figure 3(c)**). Increases in minimum temperatures and declines in maximum temperature might lead to no change in mean annual air temperature in the central part of the Corn Belt region. However, increases in minimum temperature in the northern part of the domain might provide better conditions for corn and soybean yields (**Figure 3(d)**).

2.12.3.2 Trends and Variability in Droughts

The author evaluated trends and variability in SPEI for 1915–2009 over the Corn Belt region (**Figure 4**). Precipitation variability helps provide the information about the abnormal dry or wet periods during the last 95 years. However, droughts often coincide with abnormal high temperatures that may result in higher evapotranspiration demands than expected. On the other hand, above-normal precipitation during the grain-filling season may attribute to cooling that can result in lower

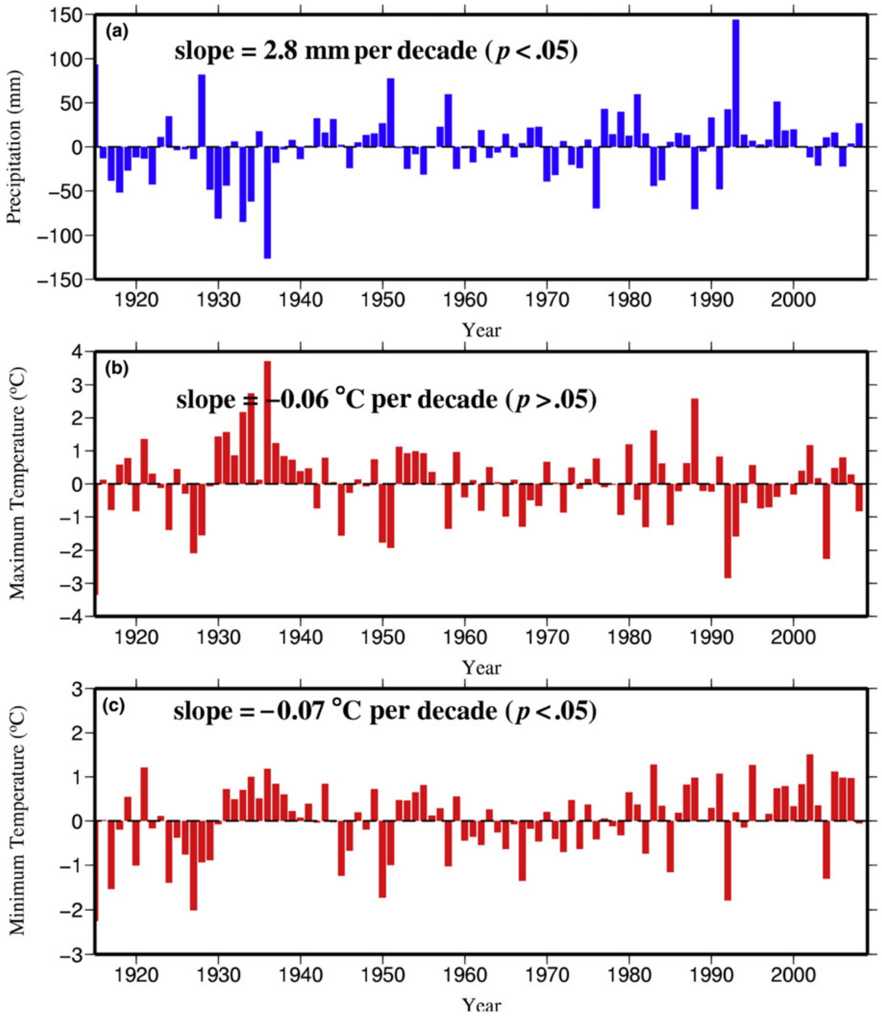

Figure 2 Domain averaged grain-filling season's precipitation and maximum and minimum temperature anomalies during the period 1915–2009. Anomalies were estimated by subtracting the long-term (1915–2009) mean from each variable. Trend slopes were estimated using the Mann-Kendall trend analysis with their statistical significance at the 5% level.

evapotranspiration demands. Because of high evapotranspiration demands, soil moisture depletes faster, which quickly translates into crop water stress. SPEI accounts for the role of temperature and therefore provides a useful measure for drought conditions during the crop growing season.

Extreme and exceptional (SPEI less than −1.6 and −2.0, respectively) droughts occurred throughout 1930–40 (Figure 4(a)). During extreme and exceptional droughts, major crop losses and sometimes entire crop damage can occur (Svoboda et al. 2002). Although the 1930s were abnormally dry, another major drought event in the Corn Belt region occurred in 1988 that severely affected crops. Abnormally high SPEI values indicate excess wetness that can be noticed in 1993 (Figure 4(a)). The 1993 flood event also adversely affected the corn and soybean crops. A positive trend in SPEI is observed which indicates that the region has experienced wetness during 1915–2009; however, the trends are not statistically significant at the 5% level. SPEI increased significantly in some parts of the Corn Belt during the last 95 years (Figure 4(b)). Increasing trends in SPEI were noticed in Illinois, Indiana, Ohio, Minnesota, Wisconsin, Michigan, Kansas, and Missouri. On the other hand, declining trends in SPEI were concentrated mainly in northern Wisconsin and the upper peninsula of Michigan.

The five most extreme drought events during 1915–2009 occurred in 1930, 1933, 1934, 1936, and 1988 (Figure 4(c)). The 1930s Dust Bowl period led the extreme drought events in the entire record. Moreover, all of these five drought events were extreme or exceptional in severity, suggesting that crop growth and production were affected severely during these events. Spatial variability of the drought composite for these five extreme dry years showed exceptional drought in southern Missouri, Illinois, Indiana, and Ohio. Moreover, parts of northern Minnesota and Iowa also experienced exceptionally dry conditions during these 5 years. During these extreme years, although most of the Corn Belt experienced extremely severe droughts, some areas in the southwest part of the domain were less affected (Figure 4(d)).

Figure 5 shows the wavelet power spectrum of SPEI during the period 1915–2009. Most of the variability in droughts was ranged between 2 and 5 years (Figure 5(a)). However, for some

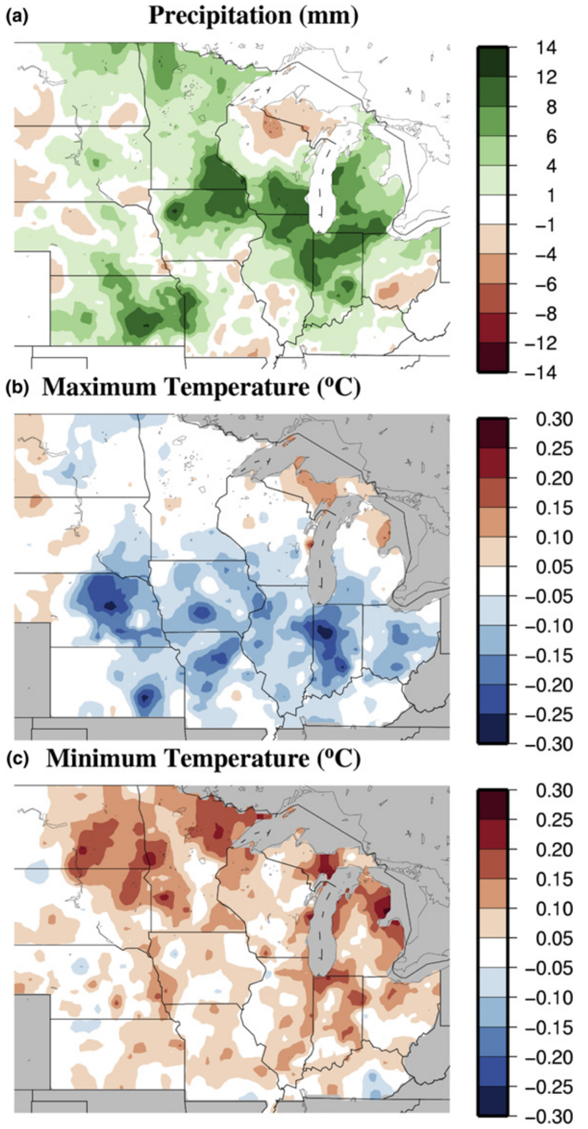

Figure 3 Decadal trends in precipitation, maximum temperature, and minimum temperature during the grain-filling seasons in the US Corn Belt. Trends were estimated for the period of 1915–2009 using the nonparametric Mann-Kendall trend method at a 5% significance level.

years (1950–60 and 1980–2000), a significant variability in the power spectrum was found in a 2- to 8-year period. The global power spectrum shows that most of the drought related variability in the Corn Belt lies between 2 and 5 years (Figure 5(b)). The variance in power was highest during the 1930s and 1988 (Figure 5(c)), whereas the period between 1940 and 1970 reflected low power variability.

2.12.3.3 Trends and Variability in Cumulative Heat

Cumulative heat during the grain-filling season provides the measure of heat stress for corn and soybean crops. The author estimated trends and variability in cumulative heat for the period 1915–2009 (Figure 5). The domain average cumulative heat for the Corn Belt highlights that the region experienced excessive heat spells during the 1930s (Figure 6(a)). Similar heat stress occurred in 1988, coinciding with the extreme drought. These results further demonstrate the concurrence of droughts and heat spells in the US Corn Belt.

Declining trends in cumulative heat were noticed during the last 95 years in the Corn Belt region. The declining trends (slope = −1.1 °C per decade, $p < .05$) in domain average cumulative heat were statistically significant during the period 1915–2009. Cumulative heat declined significantly in the central part of the Corn Belt region (Figure 6(b)). This portion of the Corn Belt also experienced a significant decline in maximum temperature and an increase in precipitation. Consistent with drought analysis, major heat spells occurred during the 1930s drought period. The top 5 years with the highest cumulative heat in the entire record of 1915–2009 were 1930, 1931, 1934, 1936, and 1988 (Figure 6(c)). All of these 5 years had cumulative heat greater than 30 °C. The cumulative heat was remarkably high during 1936 (cumulative heat ~150 °C). During the recent decade, the Corn Belt region

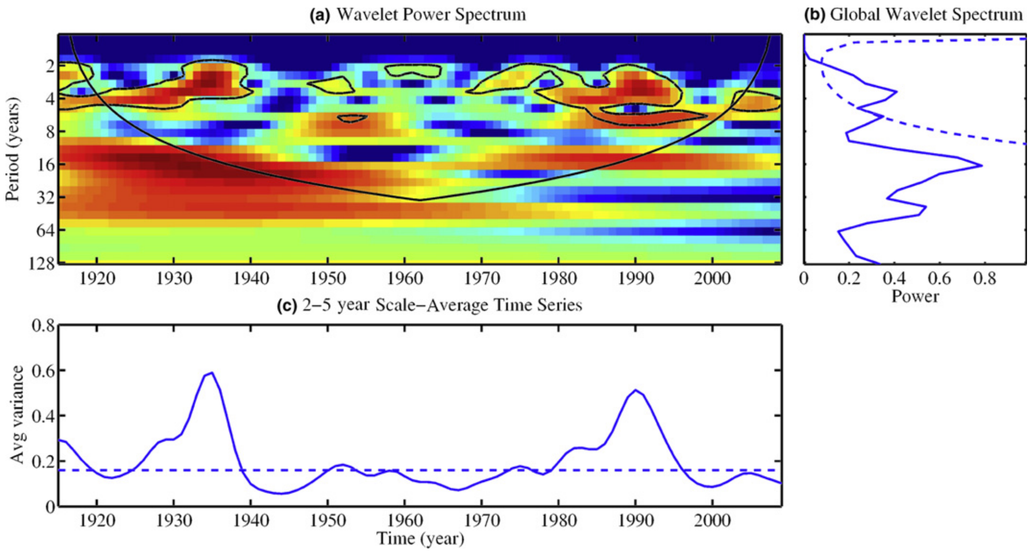

Figure 5 (a) Wavelet power spectrum for SPEI. (b) Global wavelet spectrum. (c) Average variance time series for a 2- to 5-year time scale. Contours in black show significant power, whereas blue dashed lines show the significant region at the 5% level.

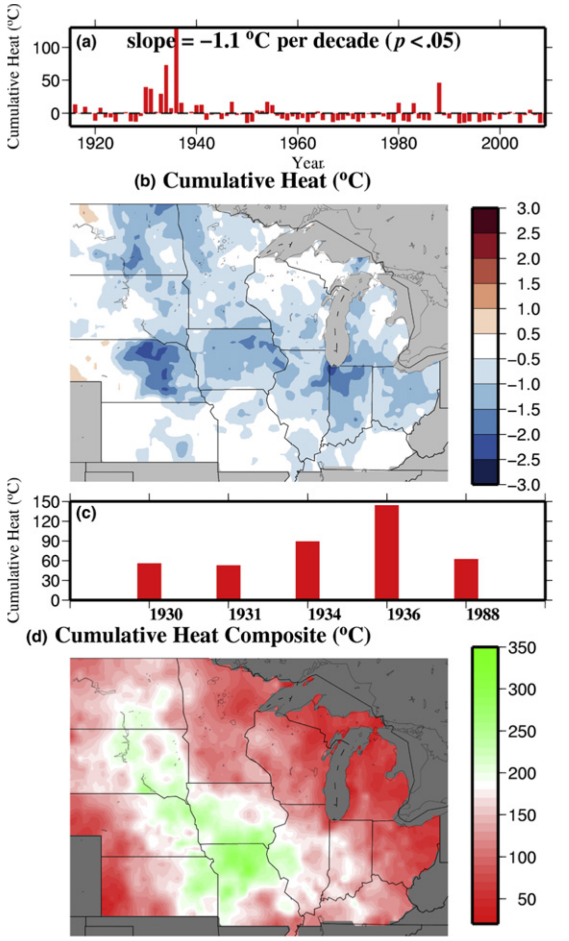

Figure 6 (a) Long-term domain averaged cumulative heat time series. (b) Spatial trends per decade in cumulative heat during 1915–2009. (c) Five most extreme cumulative heat years during 1915–2009. (d) Cumulative heat composite of five extreme historic droughts.

experienced high cumulative heat in 1988 drought during the grain-filling season. Composite analysis for the extreme cumulative heat years showed that cumulative heat varied between 50 and 350 °C. Although mean cumulative heat was between 40 and 100 °C for most of the Corn Belt, the cumulative heat peaked at greater than 300 °C in parts of Iowa, Missouri, Kansas, and Nebraska (Figure 6(d)).

The wavelet power spectrum for cumulative heat during the period 1915–2009 is presented in Figure 7. Wavelet power spectrum and global power spectra show that most of the variability in cumulative heat lies in the 2- to 5-year period (Figure 7(a) and 7(b)). Significant variance in power of cumulative heat occurred during 1930s and between 1980 and 1990. Both of these periods were influenced by ‘extreme’ and ‘exceptional’ droughts. The period between 1950 and 1980 showed the low variance in power of cumulative heat and therefore can be considered as a relatively heat spell-free period. Average variance in two extreme hot and dry periods (1930s and 1988) was significant; however, there was a substantial difference in the magnitude of variance (Figure 7(c)).

2.12.3.4 Trends and Variability in Growing Degree-Day

Growing degree-days (GDD) for corn and soybean crops during the period 1915–2009 are presented in Figure 8. GDD were anomalously high during the 1930s when the Corn Belt region experienced higher GDD by 200 to 300 degree-days above normal (Figure 8(a)). Other high GDD phases were noticed during 1920s, late 1950s, 1988, and late 2000. Between 1915 and 2009, GDD increased with a rate of 1.1 degree-day per decade; however, this increase in GDD was not significant at the 5% level.

Spatial trends in GDD suggested a substantial increase in the Northern domain of the Corn Belt region (Figure 8(b)). Remarkably, the northern part of the region experienced increases in GDD that varied between 5 and 35 degree-days per decade. These changes can be attributed to increases in the

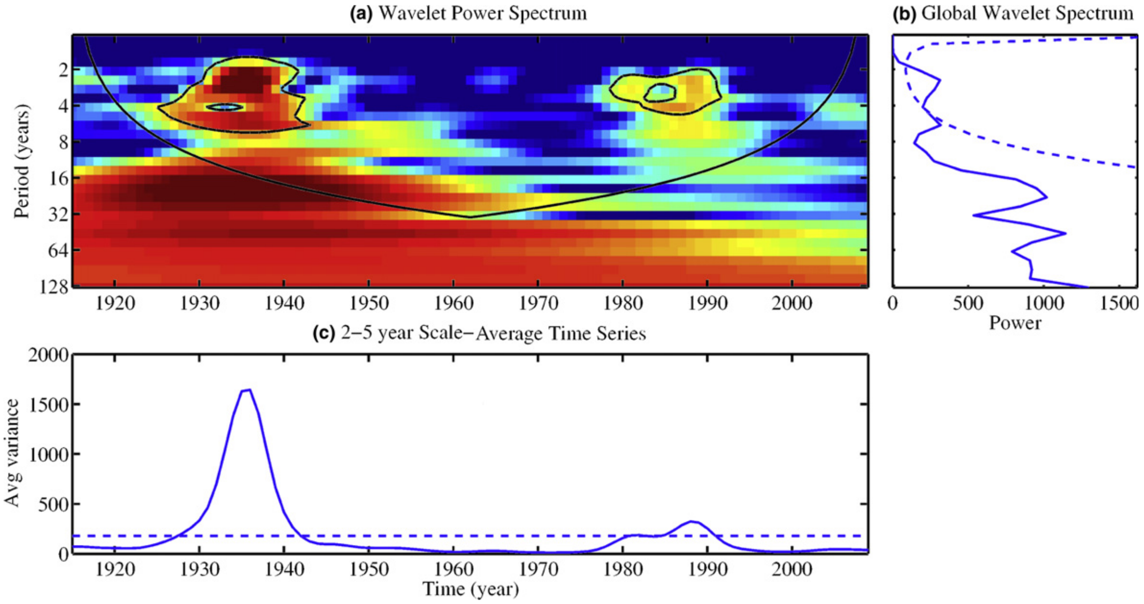

Figure 7 (a) Wavelet power spectrum for cumulative heat. (b) Global wavelet spectrum. (c) Average variance time series for a 2- to 5-year time scale. Contours in black show significant power, whereas blue dashed lines show the significant region at a 5% level.

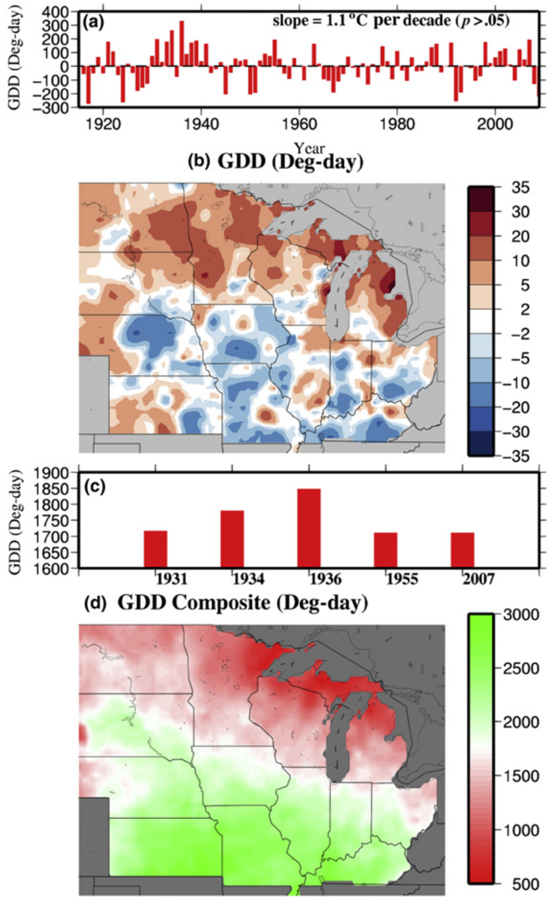

Figure 8 (a) Long-term domain averaged growing degree-day (GDD) time series. (b) Spatial trends per decade in GDD during 1915–2009. (c) Five most extreme GDD years during 1915–2009. (d) GDD composite of five extreme historic droughts.

minimum temperature in the northern part of the region. Increases in the minimum temperature might result in increases in frost-free period and therefore increases in the growing season length. On the other hand, declining trends in GDD in the central part of the Corn Belt region could be attributed to decreases in maximum temperature as well as increases in precipitation. The five largest GDD years for the Corn Belt region during the 1915–2009 period were 1931, 1934, 1936, 1955, and 2007 (Figure 8(c)). Similar to other variables, the author found that the five highest GDD years were largely outnumbered by the 1930 hot and dry period. Interestingly, the other major drought event (1988) was not recorded as the one with the highest GDDs. Strong North–South variability in GDD was found in the composite of GDD (Figure 8(d)). Mean GDD during the five extremes varied between 500 and 3000 degree-days. The GDDs were lower in the northern domain and higher in the southern part of the Corn Belt that can be attributed to differences in mean air temperature as well as the length of the growing season.

The wavelet power spectrum for GDD showed relatively higher variability in interdecadal time scales (Figure 9(a)). Similar to SPEI and cumulative heat, most of the variability in GDD lies in 2- to 5-year and 2- to 8-year time scales (Figure 9(a) and 9(b)). The significant variance in power of GDD was found for 1915–30, 1930–40, 1943–55, 1988–95, and after 2000 (Figure 9(c)). The period between 1956 and 1988 showed relatively lower variance in power of GDD.

2.12.3.5 Climate and Crop Yields

Figure 10 shows the variability in precipitation and the relationship of climate variables with the domain average corn yields during the period 1980–2009. Corn yields have increased historically, which can be attributed to improved management and technologic advancement, as well as

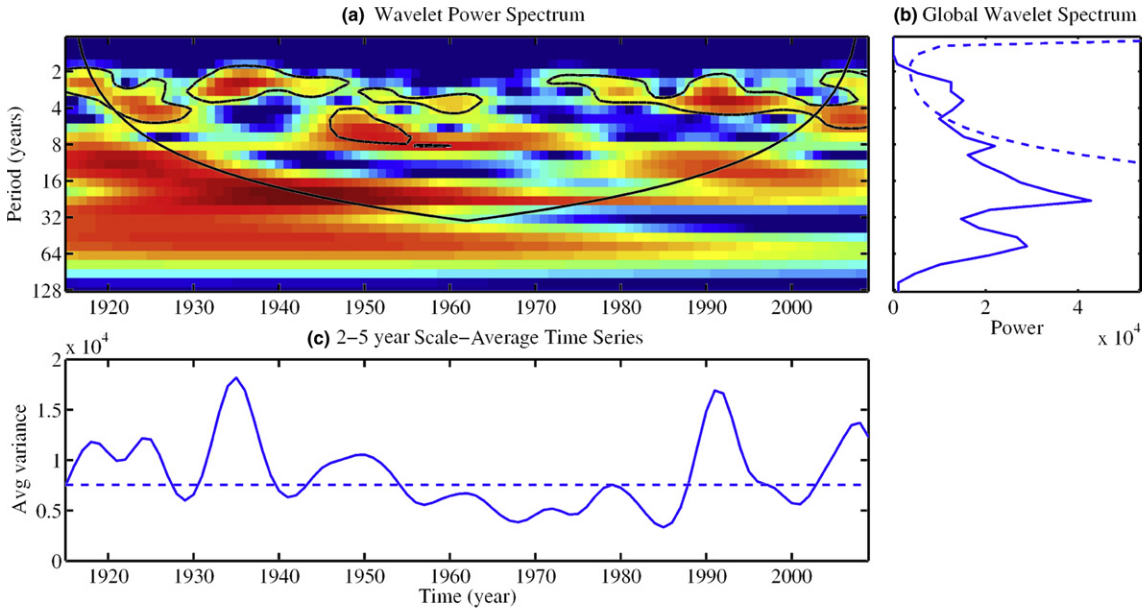

Figure 9 (a) Wavelet power spectrum for growing degree-days. (b) Global wavelet spectrum. (c) Average variance time series for a 2- to 5-year time scale. Contours in black show significant power, whereas blue dashed lines show the significant region at a 5% level.

improvements in seed varieties. To evaluate the climate impacts on corn yields, we selected the recent three decades, as the yields were somewhat less influenced by technology. Moreover, this period has two extreme years: the drought event in 1988 and the 1993 flood event (Figure 10(a)).

The variability in precipitation beyond one and two standard deviations severely affects corn yields (Figure 10(b)). For instance, the corn yields are very weakly related ($R^2 = 0.03$) to precipitation during the grain-filling season. In general, above-normal precipitation supports corn yields; however, the 1993 flood event (when the precipitation exceeded two standard deviations from the mean) adversely affected the corn yields. Because of the presence of this extreme flood event, the relationship between precipitation and corn yields became weaker. On the other hand, both maximum and minimum temperatures during the grain-filling seasons showed a stronger relationship with corn yields (Figure 10(c) and 10(d)). Above average temperatures during the grain-filling season lead to a reduction in crop yields. The SPEI that accounts for both deficits in precipitation and the influence of abnormal temperature shows better relationship with the corn yields than precipitation (Figure 10(e)). However, the cumulative heat showed the best relationship with corn yields (Figure 10(f)). However, GDD was weakly related to the crop yields (Figure 10(g)).

The relationship between soybean yields and climate variables is shown in Figure 8. Soybean yields are less influenced by the climate variability than corn yields. For instance, the influence of abnormal air temperature on soybean yields is substantially lower than those on corn yields. These differences can be attributed to the physiologic as well as phenologic dissimilarities in corn and soybean crops. The CUM_HEAT and maximum air temperature showed better relationship with soybean yields with coefficient of determination 0.34 and 0.27, respectively (Figure 11(c) and 11(f)). Among the fitted explanatory variables for corn and soybean yields, CUM_HEAT appears to be a better predictor than other climatic variables (i.e., precipitation, temperature, and GDD) in the United States.

The author also evaluated the multiple regression approach to estimate the change in crop yields owing to changes in the selected climate variables. From the stepwise regression, cumulative heat during the growing season explained most of the variability in corn and soybean yields during 1980–2009. The improvement in the coefficient of determination using the other variables (e.g., precipitation, TMAX, TMIN, SPEI, and GDD) was not statistically significant. One possible reason for this might be the degree of cross-correlation among the selected climate variables during the grain-filling season (Table 1). Cumulative heat during the grain- the author found that a 10 °C increase in cumulative heat in the grain-filling season leads to 6.2 and 1 bu per acre reductions in corn and soybean yields, respectively. A 10 °C increase in cumulative heat can be considered as 10 days with daily maximum temperature 1 °C warmer than the 90th percentile of the period 1961–90. Moreover, reoccurrence of a similar heat spell that occurred during the 1988 drought (cumulative heats were higher by about 50 °C than mean) may lead to 38 and 7 bu per acre reductions in corn and soybean yields, respectively.

2.12.3.6 Recent Climate Trends and Yield Impacts

To evaluate whether climate during the last three decades (1980–2009) has contributed to corn and soybean yields substantially, the relationship between crop yields and cumulative heat (Table 2) was used to identify the climate contribution (Figure 12). As the estimated loss in crop production is sensitive to the period of analysis (Lobell and Field 2007), the minimum 15-year period was used starting

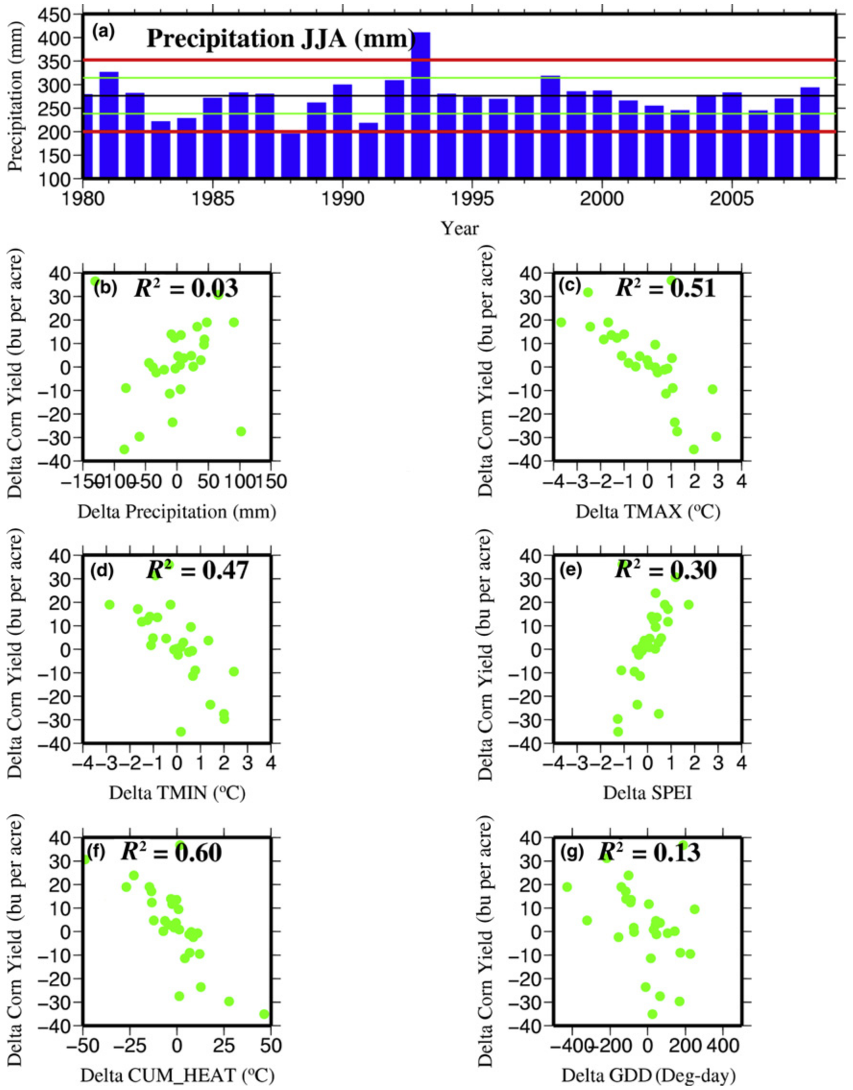

Figure 10 (a) Precipitation variability in the US Corn Belt region during 1980–2009. Red lines indicate two standard deviations from mean, and green lines indicate the range of one standard deviation from the mean, (b–g) relationship between change in climate variables and corn yield.

from 1980 with all possible ending years till 2009 (e.g., 1980–94, 1980–95, …, and 1980–2009). Changes in cumulative heat were used to analyze its impacts on crop yields using the regression relationship.

Impacts of recent changes in cumulative heat indicated a wide range of uncertainty in crop yields for corn and soybean (Figure 12(a) and 12(b)). However, the mean impact of changes was positive until 2000 for both the crops. After 2000, as reflected by the results, the 95% confidence interval of changes in yield showed both positive and negative values. The net impacts of climate on crop yields were largely positive for both corn and soybean crops, which can be attributed to possible cooling in the US Corn Belt.

2.12.3.6.1 Discussion and Conclusions

This chapter discussed climate and its influence on crop yields in the US Corn Belt. Long-term (1915–2009) analysis of climate (precipitation, maximum and minimum temperatures) and the selected climate indices reflected a wide range of variability in climatic trends that might have implications for corn and soybean production. There have been significant increases in precipitation and mean annual minimum temperature in the grain-filling season during the last 95 years. Results indicated nonsignificant cooling trends in mean annual maximum temperature during the period 1915–2009. Climatic trends influenced indices relevant to the crop production in the US Corn Belt. For instance, the frequency and severity of severe, extreme, and exceptional droughts seem to have declined but not been eliminated during the recent period. Although reduction in the maximum temperature was not statistically significant, it resulted in reduced heat stress during the grain-filling season. On the other hand, significant increases in mean annual minimum temperatures in the northern part of the domain have contributed to increases in growing degree-days. Consistent with trends in minimum temperature, more

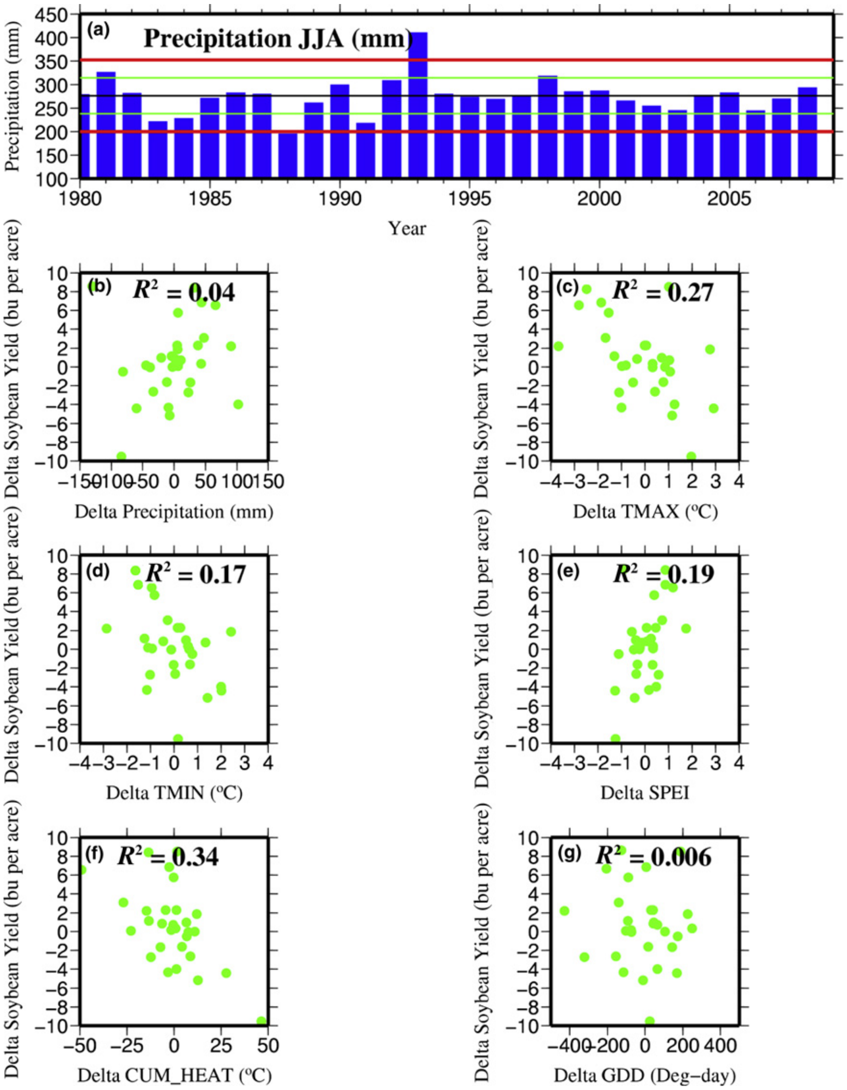

Figure 11 (a) Precipitation variability in the US Corn Belt region during 1980–2009. Red lines indicate two standard deviation from mean, and green lines indicate the range of one standard deviation from the mean, (b–g) relationship between change in climate variables and soybean yield.

Table 1 Correlations among climate variables during the grain-filling season

Variable	*Precipitation*	*TMAX*	*TMIN*	*SPEI*
Precipitation	1			
TMAX	−0.54	1		
TMIN	−0.19	0.9	1	
SPEI	0.88	−0.86	−0.67	1
CUM_HEAT	−0.58	0.78	0.54	−0.77

prominent increases in GDD were noticed in the northern part of the US Corn Belt. The trends in long-term climate with declining droughts, increasing precipitation, cooling of TMAX, increases in GDD in the northern domain, and declining heat stress in the central domain indicate more supportive climate for corn and soybean production in the US Corn Belt. Long-term analysis suggested that most of the extreme events (droughts and heat spells) occurred during the 1930s. The severity of droughts and heat spells that occurred during the 1930s remained unmatched in the last 95 years. For instance, four out of five most extreme droughts and heat spells occurred during the 1930s. The only event that fell in the five most extremes occurred in 1988. Drought severities and heat stress during the 1930s were about twice as high as those that occurred in 1988. Drought and heat stress during the 1988 grain-filling season severely affected corn and soybean production in the region. For instance, a 30% reduction in crop production was noticed during the 1988 drought (Rosenzweig et al. 2001). Reoccurrence of drought like that of the 1930s and 1988 could be even more detrimental for corn and soybean production. This is mainly because of increases in corn and soybean yields that the region experienced during the recent decades. This analysis shows that a similar heat stress to that of 1988 could lead to

Table 2 Linear regression relationships between crop yield and cumulative heat

Crop	*Intercept*[a]	*Slope*[a]	*Equation*
Corn	1.75 (−2.5, 6.0)	−0.8 (−1.0, −0.5)	Delta $Y = 1.75 - 0.8^a$ Delta CUM_HEAT ($R^2 = 0.60$, $p < .05$)
Soybean	0.38 (−0.9, 1.7)	−0.14 (−0.22, −0.06)	Delta $Y = 0.38 – 0.14^a$ Delta CUM_HEAT ($R^2 = 0.34$, $p < .05$)

[a] *Values in parenthesis indicate a 95% confidence interval.*

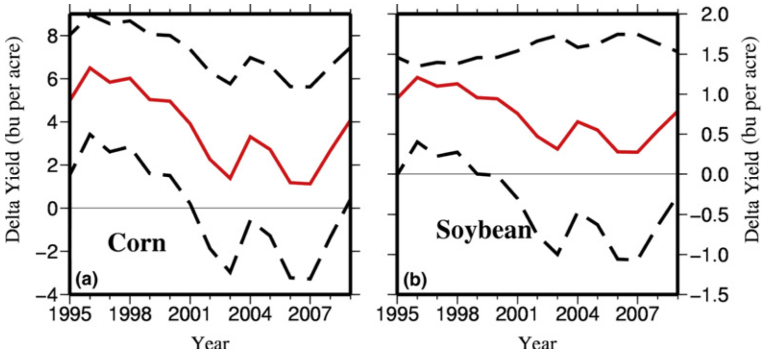

Figure 12 (a) Effect of climate on corn yields. (b) Effect of climate on soybean yield. The red line indicates estimates based on mean climate, whereas the black lines show the 95% confidence interval. Changes in cumulative heat were computed starting from 1980 until 2009, with a minimum of 15 years of analysis.

reduction of 38 and 7 bu per acre in corn and soybean yields, respectively.

Results indicate that the climatic patterns during the last 30 years have been largely supportive of corn and soybean production. However, increases in floods during the grain-filling season can severely affect the corn and soybean yields in the region. For instance, the 1993 flood caused $6–8 billion damage to farmers (FEMA 1995). Moreover, floods that occur in the early crop-growing season often delay the planting of crops, resulting in losses in crop yields. It was found that an increase or decline in precipitation more than one standard deviation from the mean affects corn and soybean crop yields dramatically (e.g., 1988 and 1993). These results are consistent with the findings of Rosenzweig et al. (2002), who reported a probability of events causing damage comparable with the 1993 flood will double by 2030 and quadruple by 2090. Further analysis is needed to understand the changes in probabilities of occurrence of floods and extreme precipitation events coinciding with the crop growing season in the US Corn Belt. More work based on regional climate vulnerabilities such as those owing to change in the frost patterns, early planting dates, and production practices are needed to better understand the impact of extreme events and potential reductions in crop production.

A strong covariance in climatic indices associated with drought, heat stress, and growing degree-day was found in the grain-filling season of the US Corn Belt. Precipitation in the grain-filling season reflected a weaker relationship with corn and soybean yields. In part this might be because of the 1993 flood event. During the 1993 flood, precipitation during the grain-filling season was two standard deviations higher than normal. The SPEI showed a stronger relationship than that of precipitation (SPI) and crop yields. Analysis of climate variables and corn and soybean yields suggested that cumulative heat during the grain-filling season can help explain the yield variability. However, the climate response on soybean yields is somewhat lower than that of corn yields.

2.13.1 Introduction

Global and regional climatic variability has the potential to cause impacts to agricultural operations around the world. For example, arid parts of the world could expand and serious constraints to crop cultivation are underway (Fischer et al. 2005). In other places, climatic shifts could create more potential agricultural land and better growing conditions if adequate soil nutrients also coexist (Fischer et al. 2005). However, the overall impacts of climatic stress may be negative and thus threaten global food security (Nelson et al. 2009). It is, therefore, critically important to assess farmers' vulnerabilities and capacities to respond to negative impacts of climatic stresses. To meet this challenge, there is a concerted effort around the world to both assess the vulnerability and adaptive capacity of farming households, as well as to better understand different ways to manage climate-related risk. This research suggests that one critical determinant of adaptive capacity of agricultural systems is the ability to use climate knowledge and decision support tools to inform preventive action and adaptation options to climate-related impacts.

This chapter reviews the literature focusing on the role of climate information use (or lack thereof) by farming households in shaping their adaptive capacity to climate impacts. It first reviews the empirical literature exploring the opportunities and constraints to use of climate information (especially Seasonal Climate Forecasts, SCFs) and how it may contribute to reduce the threat of climatic vulnerability to farming. It then discusses how this literature has assessed vulnerabilities and adaptation approaches and the social science research methods used. Finally, it concludes with an example of how social science data can be combined with climate modeling to reduce vulnerabilities and enhance adaptive capacities.

2.13.2 Vulnerability and Adaptive Capacity

The IPCC (2007) defines vulnerability as a function of a system's exposure, sensitivity, and adaptive capacity to climate impact; that is, vulnerability refers to "… the exposure and sensitivity of [a] system to hazardous conditions and the ability … of the system to cope, adapt or recover from the effects of those conditions" (Smit and Wandel 2006, p. 286). Adaptive capacity, in turn, is defined as "the potential or ability of a system, region, or community to adapt to the effects or impacts of climate change" (Reid et al. 2007, p. 612). (**Table 1** shows common determinants of adaptive capacity.) Hence, the vulnerability of farmers to drought, for example, depends on how exposed and sensitive they are to the event and how much capacity they have to respond and recover after it happens (IPCC 2007). The three dimensions of vulnerability – exposure, sensitivity, and adaptive capacity – are shaped not just by the magnitude and frequency of the climate event, but also by the timing and the multitude of deficits and capacities farming households have to cope with or adapt to climate stress. From this perspective, vulnerability is not a static concept, but varies

Table 1 Determinants of adaptive capacity

Determinant	*Description*
Awareness	The ability to accurately identify the signals of change and their implications
Technology	The availability of and access to technologic options for adaptation
Resources	The availability of resources for adapting (including financial capital and physical resources)
Institutions	The structure of critical institutions, including the allocation of decision-making authority
Human capital	The skills, education, experiences, and general abilities of individuals
Social capital	The informal social networks and collective life of a community, as it influences the ability and willingness of residents to work together for common community goals
Risk management	The ability of a system to manage risks, including sharing the risk among the stakeholders
Information management	The ability of decision makers to manage information, including the processes by which information is acquired and assessed

both spatially and temporally, by livelihood system and socioeconomic group (Liverman 1999; Vásquez-León 2002).

Regarding adaptation, how farmers have responded to climate variability in the past has often informed our understanding of how they might respond in the future. For example, based on past response, Agrawal (2008) has suggested a typology of five categories of adaptation strategies to climate stress among poor farmers: diversification, mobility (e.g., migration), storage, communal pooling, and exchange. Among resource-richer farmers, other options to manage risk include buying farm insurance and proactive planning using decision support tools such as SCFs. Table 1 describes common determinants of adaptive capacity.

This chapter specifically reviews the role of SCFs as a determinant of adaptive capacity and examines the different research methods the empirical social science literature has employed in understanding the vulnerabilities and capacities of farming households and the potential role for climate information to modulate them.

2.13.3 Literature Review: Vulnerability, Adaptive Capacity, and Climate Information

The ability to forecast or project climate (short-term epochs, seasonal, and long term) and plan ahead has often been assumed to be critical to decreasing farming systems' vulnerability. The rationale is that if farmers know about the potential negative impact of the meteorologic events ahead of time, they can protect their crops (e.g., from frost and floods), apply climate-resistant technology (e.g., plant drought-resistant varieties or crops or use irrigation), pool risk (e.g., through diversification or storage), or buy insurance that would allow them to recover and start over. All these actions in principle increase their adaptive capacity; that is, their ability to prevent, cope, and recover from climate-related negative impact. Not surprisingly, through history, farmers have consistently devised different ways to predict climatic patterns to prevent and respond to their negative effects. However, the challenge of predicting climate is well documented and different approaches, from folk forecasts to scientific modeling, carry substantial levels of uncertainty that modulate their usefulness to farmers and other decision makers (e.g., see Lemos and Rood 2010). Although there has been significant investment in understanding the usability of climate forecasts around the world, relatively little is known about how climate information has affected the overall vulnerability of farmers. Rather than assessing outcomes of forecast use, most of the research so far has focused on understanding whether and why farmers use climate information or not.

For the past 30 years, one particular kind of climate prediction, seasonal climate forecasting has been the subject of significant research, especially in the social sciences, to understand the opportunities and constraints of using emerging technology to forecast climate up to a year in advance. Part of the motivation for this research has been to assess the value of forecasts as a decision-support tool. For example, while researching farmers in Florida, Cabrera et al. (2007) sought to estimate the value of climate information in reducing farm risk by helping farmers decide on management strategies that could both reduce negative impacts of climatic shifts, but also know when to take advantage of changes in weather conditions that would be more favorable for growing than expected given past conditions. Another goal of empirical research has been to use evidence from SCF application as an analog to understand potential challenges to the use of other kinds of climate information, especially global climate projections.

2.13.3.1 Seasonal Climate Forecasts as a Decision Support Tool

Since becoming available in the 1990s, various studies have consistently extolled the potential value of seasonal climate forecasts (Zebiak and Cane 1987; Magalhães et al. 1988; Glantz 1996; Ropelewski and Lyon 2003; Harrison 2005) to decrease farming vulnerability. In the mid-1980s, scientists interested in climate dynamics discovered the mechanisms of the El Niño-Southern Oscillation (ENSO) phenomenon well enough to be able to predict the onset of its warm (El Niño) or cool (La Niña) phase several months to even a year in advance. The ENSO phenomenon and its teleconnections wreak havoc on many tropical and subtropical regions of the world, disrupting normal patterns of rainfall to cause severe droughts and catastrophic flooding. The possibilities raised by climate scientists and policy makers alike that such a devastating climate variability could be anticipated and planned for were very appealing, especially if the worst climate-related impacts on poor populations worldwide could be avoided (Broad et al. 2002).

Although scientists did have some spectacular breakthroughs in ENSO predictability in the past two decades, the reality on the ground soon tempered the initial expectations. On the one hand, some users have been able to benefit from this new information. For example, many Pacific Island nations respond to El Niño outlooks and avoid potential disasters from water shortages; similarly, agricultural producers in Australia and the United States have been better able to cope with swings in their commodity production associated with drought (Hammer et al. 2001; Hartmann et al. 2002; Pagano et al. 2002; Hogan et al. 2010). On the other hand, these uses have been mostly in more developed regions and within well-funded and resourced groups in society. However, even in more developed countries such as the United States, documented SCF use among farmers has been low. For example, coming from similar perspectives, Hu et al. (2006), and PytlikZillig et al. (2010) have argued that overall, farmers' attitudes toward SFC use have remained poor and actual use has not increased despite improvements in climate predictions. Moreover, US farmers report a low level of understanding concerning climate variability and attach higher importance to short-term weather impacts at local spatial scales. In less developed regions, more often than not, the poorest of the poor have not benefited from the development of SCFs and, in some instances, have actually been negatively affected by it. For example, in Peru fishing companies have used SFC as one input to lay off workers when facing the possibility of a weak season and in NE Brazil, rain fed farmers' access to selected seed has been conditioned to a favorable forecast by the government (for a more detailed description see Broad et al. 2002; Lemos 2003).

2.13.3.2 Usability of SCFs

In theory, SCFs have many applications including supporting agricultural planning, water management, and disaster preparedness and response. In assessing the value of SCFs for the past 15 years, a rich empirical literature focusing on different sectors in different parts of the developed and developing worlds has emerged both in the social and natural sciences (Zebiak and Cane 1987; Pagano et al. 2002; Johnston et al. 2004; Harrison 2005; Vogel and O'Brien 2006; Lemos and Dilling 2007; Meinke et al. 2008; Gilles and Valdivia 2009; Roncoli et al. 2009; Hu et al. 2006; PytlikZillig et al. 2010). Findings from this literature suggest that successful application of SCF tends to follow a systems approach in which the SCF is contextualized to the decision situation and embedded within an array of other information relevant for risk management (Lemos and Dilling 2007). However, in practice, climate information is often perceived as 'outside' of the experience and routine of decision makers. For example, in the United States, PytlikZillig et al. (2010) contend that a significant hurdle to forecast use by farmers is that information about climate forecasts and tools is typically available in situations other than their "day-to-day activities and actual experiences" (p. 1334). In other words, climate information and forecasts are typically presented out of context, and therefore less useful for agricultural adaptation than they could be.

Research also finds that institutional and organizational factors play a critical role in fostering or constraining the use of SCFs in different sectors. In the Pacific Northwest US, environmental regulation (e.g., Endangered Species Act) has critically constrained the ability of decision makers to apply SCFs because it limited the range of decisions that could be made to guarantee compliance (Callahan et al. 1999). In Florida, Cabrera et al. (2007) found that government farm programs may be limiting (or failing to encourage) farmers' use of climate information by restricting the types of crops farmers can grow, and by raising crop prices that encourage larger monoculture farms that are less adaptable to climate variability. In addition, programs that seek to stabilize farm income tend to reduce farmers' perceptions of risk and urgency to adapt to climatic shifts (Cabrera et al. 2007).

Another critical finding from this literature is that the value of SCFs is fundamentally dependent on different users' ability, capacity, and willingness to respond to SCFs. Even if potential users have access to information, they may be powerless or unwilling to respond effectively. This applies both for highly regulated, wealthy institutions and for those individuals and groups living on the margin of survival. Much has been written, for example, on the lack of institutional capacity to respond to improved scientific predictions of stream flow, seasonal weather patterns, and climate (Pulwarty and Redmond 1997; Rayner et al. 2005). In the United States, water managers constrained by the high levels of accountability of their decision environment, prefer to rely on their professional experience rather than on SCFs to guide their management decisions (O'Connor et al. 2005; Rayner et al. 2005). Just having better information available does not necessarily lead to an improved response. For example, in the United States, Hu et al. (2006) found that changes to external factors (such as the accuracy of forecasts) have not resulted in increased use of information and adaptation by farmers, and argue that the focus of research should shift to understanding 'internal' reasons for using or not using forecasts – social and psychological factors – from the farmers' perspective. Similarly, among poor farmers in Africa and Latin America, the general lack of alternatives both in terms of technology and access to financial and human resources act as a critical constraint to their ability to use SCFs. Lack of resources among the most climate-vulnerable rain-fed farmers also curbs their ability to respond to forecasts even if they have access to them (Hammer et al. 2001; Ingram et al. 2002; Lemos et al. 2002). Similarly, extreme adaptive strategies such as changing livestock species are often not considered because of the risk, cost, and time involved in making such significant changes (Coles and Scott 2009). Other factors, such as perception of climate change, membership in networks, belief that information use will lead to economic and environmental benefits, and cultural traits and contexts. Credibility of the information and those producing it also influence willingness to use climate information (Roncoli 2006, Hu et al. 2006; Crane et al. 2010, Marshall et al. 2011).

Significant effort has been put into projects to help potential beneficiaries of SCFs realize those benefits, in both wealthy and poor regions. Importantly, successes are usually associated with an infusion of additional resources that potential users of SCFs were lacking in the first place, along with the new technology of SCFs (Lemos and Dilling 2007). For the systems/contextualized approach to work, participants usually have to have not only financial resources to come to meetings and access to information through the media, but must also be within the 'radar' of organizers of workshops; that is, the selection of potential users is often connected to specific implementation projects rather than widespread dissemination. When resources are available, interaction between model developers and users has been found to be the most critical factor driving usability. For example, in-depth studies of climate information use among water managers in the United States show that interaction between producers and users fundamentally influences the willingness of decision makers to apply climate information to their decision-making process (Engle 2010; Kirchhoff 2010). In Arizona, decision makers reported higher interest in using climate information after being given the opportunity to interact with climate model developers in a controlled social experiment (White et al. 2010). In Burkina Faso, a long-term SCF application project reported significant increase in use among poor rain-fed farmers after repeated interaction between project members and farmers (Roncoli et al. 2009). In Nebraska, farmers were more motivated to use forecasts or decision support tools when they felt they contributed to it; that is, when they have a sense of 'ownership' of the information rather than passively receiving it (PytlikZillig et al. 2010).

Based on this rich empirical research, different studies have advanced a range of recommendations to increase climate information use, especially if the goal is to decrease farmers' vulnerability. First, they recommend that predictions should be integrated into broader decision contexts that should take into consideration not just the magnitude and dimension of exposure to climate impacts, but also the sensitivities related to livelihoods, institutions, politics, cultures, and economic situation of potential users (Johnston et al. 2004; Klopper et al. 2006; Meinke et al. 2008; Roncoli et al. 2009). Thus, rather than providing forecasts as a 'fix,' governments should be supporting farmers to adapt sustainably (Hogan et al. 2010). Second, they suggest that proactive strategies rather than reactive ones should be encouraged. In Florida, Cabrera et al. suggest that seasonal climate forecasts would be most useful when they provide farmers with 'offensive' strategies that allow them to capitalize on favorable conditions, and for farmers who are more risk averse. In contrast, crop insurance and/or commodity loans while alleviating risk, make climate information seem less valuable to farmers. Third, communication, availability, perception of accuracy, training and credibility needs to be improved; for example, by targeting groups who have the most influence of farmers' choice (Hu et al. 2006; Crane et al. 2010; Artikov et al. 2006).

2.13.4 Assessing Vulnerabilities and Adaptive Capacities

As described, many studies have argued that understanding what motivates and limits the use of SCFs is not simple and involves accessing underlying social and psychological factors (Artikov et al. 2006; Hu et al. 2006; Marshall et al. 2011). To that end, a variety of social science methods have been used to try to understand farming systems' adaptive capacity and perceived vulnerabilities to climate change. In recent years, many vulnerability studies have covered a wide spectrum of risks and hazards while stimulating a rich debate about the many conceptual approaches to vulnerability and the methods to assess and measure it. Several factors contribute to the lack of consistency in the literature, including the multitude of disciplines and communities involved, the different contexts, scales, and areas of analysis, and diverging sources of methodology (Bohle 2001 cited by Kasperson and Kasperson 2001). One issue of particular debate is the dichotomy between top-down/ground-up strategies of vulnerability analysis. Although top-down approaches predominate in the literature, increasingly studies agree that there is a need to combine global/national level data with ethnographic and household survey approaches from the ground. For example, in their evaluation of vulnerability assessment methods for food security, Stephen and Downing (2001, p. 115) point out that socioeconomic indicators only contribute to one part of an entire information system. Hence, currently predominant assessments models look at climate hazard as one among many other stressors that shape farming households' vulnerability. This chapter reviews the most commonly used research methods to assess farmers' vulnerability, paying special attention to the strengths and weaknesses of these approaches.

An important consideration in conducting research about agricultural vulnerability and adaptive capacity is research design. The selected research design drives decisions about appropriate methods to use to collect information (Prokopy 2011). The choice of research design should be driven by theory and the research questions one is trying to answer. Research designs can include cross-sectional (one point in time) and longitudinal data collection. They can include experimental designs and case studies. One of the considerations in research design is 'unit of analysis'; that is, who is the subject of the study.

2.13.4.1 Who Is the Subject of the Study?

Despite the fact that many actors make decisions that influence farming systems' vulnerability and adaptive capacity, most research on this topic focuses on the farmer or the farming household as the unit of analysis. Figure 1 illustrates the many different scales of decision making and factors that influence the choice of farming practices (crop variety, fertilization choices, planting time, access to technology, etc.). Although the landowner and/or operator usually make the majority of farming decisions, they are influenced by both family members and advisors (e.g., extension agents, crop consultants) (Coles and Scott 2009; Hu et al. 2006). In turn, people making and influencing decisions are informed by the larger policy environment and past experiences, including past climatic conditions. The decisions themselves are shaped by farm characteristics such as farm size, soil quality, access to water, and so on. In any study to assess vulnerabilities and adaptive capacity, the starting point is to determine *who* to study.

Figure 1 Different scales of decision making and factors that influence choice of farming practices.

2.13.4.2 Acquiring a Sampling Frame

A sampling frame is a complete list of all people meeting the criteria determined by the study. For studies in which generalizability to a complete population is the goal, a random sample or census of this population will usually be assessed. For studies in which in-depth understanding is desired, developing a random sampling frame is less important and results from nonrandom sampling approaches (e.g., snowballing, purposive sampling – in which subjects are chosen because of some desirable characteristic) are likely to be less generalizable to other contexts.

Finding a sampling frame for conventional farmers in developed countries can be relatively straightforward. For example, Smit et al. (1996) were able to access a list of all farmers in three townships in southwestern Ontario through municipal office records for their quantitative farmer climatic variation adaptation survey. However, finding a sampling frame for nontraditional farmers may be more difficult. Smaller and more diverse farms are less likely to participate in government programs (Nickerson and Hand 2009). Also, because of barriers to certified organic adoption (Constance and Choi 2010), many farms that are essentially organic are not certified. One solution in the United States is to access publically available county landowner records. By surveying all landowners with more than five acres in a particular geographic location, one captures the majority of the nontraditional farming study population. However, this strategy introduces elements who are not part of the study population (nonagricultural landowners). Although these data can be discarded, this method may result in a substantial waste of money and time.

2.13.4.3 Probability Sampling

For quantitative research to be generalizable to a larger population, a probability sampling method must be used. The most basic probability sampling method is simple random sampling, in which the people to be studied are selected from the complete sampling frame only by chance. Generally, this method involves using a computer program to assign each case a number and then generate a random selection of the appropriate sample size.

One problem with simple random sampling is that certain strata in a population might not be well represented in the sample. For example, to compare farmers in the United States based on ethnicity, a simple random sample of farmers is not likely to result in an adequate number of minority farmers for comparisons to be made. In this case, disproportionate stratified sampling is needed. In other words, the sampling frame is divided on the basis of a particular stratum, which in this case is ethnicity. Then, each section of the sampling frame is sampled randomly, but not in proportion to the representation of each stratum (i.e., ethnicity) in the population. That is, a higher proportion of the less common strata will be selected than by simple random selection, so that each stratum is well represented in the sample.

2.13.4.4 Nonprobability Sampling

Although quantitative methods require large randomly selected samples, qualitative methods are more appropriate for small samples that are selected purposefully (Patton 2002). Magistro and Roncoli (2001) suggest that "a more localized, detailed understanding of a given geographical setting reflects the complexity of real life decisions and situations" regarding human adaptation to climate (p. 92).

There are many strategies for selecting a sample in qualitative research. Key informants, or people who are knowledgeable or important in the community, and who are willing to cooperate with researchers, are often excellent subjects to interview. In situations in which the researcher does not know how to reach the appropriate sample or does not have enough cases in the sample, snowball sampling may be advantageous. In snowball sampling, the researcher asks each respondent to recommend other potential respondents (Patton 2002). Snowball sampling can, however, result in sampling bias. For example, Coles and Scott (2009) found that 'snowballing' to augment their sample of southeastern Arizona farmers and ranchers may have "resulted in a set of respondents that are more connected and informed than in general" (p. 300). In this case, some variability that would have been present with a more random sample is desired.

2.13.5 Methods

In general, the purpose of a study drives the choice of the appropriate social science method(s). If the purpose of the study is actually to change behavior, then participatory research may be most appropriate (Roncoli 2006), although other methods often have behavior change as a goal. Many studies will use a mixed-methods approach (use of more than one method, such as interviews followed by a survey) to develop a more comprehensive understanding of the issue.

2.13.5.1 Surveys

Surveys generally consist of a questionnaire administered through the mail, over the phone, on the Internet, or in person. The mode(s) used depend on characteristics of the target population, the information (addresses, phone numbers, e-mails, etc.) contained in the sampling frame, and the resources (money, staff, time, etc.) available to the researcher. At times, multiple modes are used for administering questionnaires to increase the response rate and therefore decrease response bias. As response rates increase, a wider diversity of people and opinions are surveyed, which makes the results more generalizable to the entire population (assuming a probability sampling approach was used). Questionnaires can consist of close-ended questions, in which people can check boxes that apply to them, or open-ended questions, in which they write out responses, or a combination of both. Considerations for developing and choosing questions include the research questions and relevant variables, the survey mode, past research and theory, and the respondents' ability and willingness to answer. Careful question development and survey formatting is important not only to response rate, but also to validity. (Are the data an accurate reflection of reality?) For a comprehensive guide to developing and administering surveys, see Dillman et al. (2009).

Many of the studies reviewed in this chapter used surveys to collect their data in the context of different theoretical and analytical approaches (Lemos et al. 2002; Hu et al. 2006; Mertz et al. 2009). Because Lemos et al. (2002) wanted to understand how different farming households used climate information to decrease their vulnerability to drought, they stratified their random sample by different geoclimatic regions in northeast Brazil. That allowed the research team to better assess how other factors beyond climatic and geographical factors (exposure) affected SCF use. Mertz et al. (2009) used a household survey to provide "the basis for a quantitative characterization of household perceptions of CCV [Climate Change and Variability], adaptation to CCV and changes in household resource management and livelihood strategies over the past 20 years" in the savanna zone of central Senegal (p. 808). In the context of these rural Senegalese villages, it was necessary for researchers to administer surveys in person. Using a mixed-methods approach, Mertz et al. (2009) also carried out informal interviews with key informants and focus groups to complement the quantitative analysis.

2.13.5.2 Interviews

One commonly adopted method to acquire more detailed and rich data in mixed methods approaches (i.e., quantitative and qualitative) are in-depth interviews. These interviews are often used in exploratory research when the relevant variables are not well defined. They are also indicated in research in which variables are not easily quantifiable and in-depth description of factors explaining outcomes are necessary. For example, if a research goal is to understand how different past experiences influence farmer's willingness to use climate information, in-depth interviewing may be a good method. The same applies for information that may require a certain level of trust between informant and interviewer. In social science research, an interview generally involves a researcher asking an interviewee open-ended questions, a format that allows the respondent to provide content and meaning to the conversation. The conversation is recorded and then transcribed or the interviewer takes notes during or after the interaction. In our examples, different approaches to qualitative interviewing have been used. For example, because note- taking can be unreliable and not always consistent, the research teams collecting data in Crane et al. (2010) chose to record and transcribe their interviews with farmers in Georgia, the United States. However, other researchers have chosen to take detailed field notes during the interviews (Coles and Scott 2009). Still other teams, such as Cabrera et al. (2006) have a group of people participate in each of their interviews and then afterward have team members compare and discuss their notes to check for consistency. Interviews can also be conducted over the phone. Format and length of interviews also vary. In their study of farmers' skill in using climate forecasts, Crane et al. (2010) used 'semistructured' interviews, which was essentially a hybridized conversational/interview guide approach. Rather than follow a structured interview guide, interviewers loosely followed a predetermined interview protocol, which "was designed to elicit information on farmers' production systems, climate-sensitive management decisions, use of weather and climate information systems, and potential application of seasonal climate forecasts" (p. 47). However, the researchers wanted interviewees to at least partly guide the conversation, allowing for a conversational flow and new perspectives and insights. Overall, with each study population, the object is to conduct as many interviews as needed to reach data saturation, or the point at which no new patterns or themes emerge from subsequent interviews.

Interview guides are also useful when moderating focus groups, a type of small group interview. Focus groups are generally conducted with groups of 6–10 people from similar backgrounds, and several focus groups are usually conducted to ensure breadth in the data. The purpose of conducting focus groups is to collect responses from people in a social context in which respondents hear the reactions of others (Patton 2002). Focus groups are often used in concert with other methods either in the exploratory phase of research or as a way to supplement other data. As previously mentioned, Hu et al. (2006) conducted focus groups with Nebraska farmers in the exploratory stage of their research to identify and define key variables that should be used later in the survey. In their study of farmer climate change adaptation in Sahel, Mertz et al. (2009) used focus group data not only to develop the list of important concepts, but also to triangulate with data from key informant interviews and household surveys.

Although focus groups offer efficiency in that numerous individuals are interviewed at one time and can be effective at getting high-quality data, there are a number of limitations. First, shy individuals or those with minority viewpoints may not have the opportunity to express their perspectives. Second, focus groups require a skilled moderator who can manage groups of people and effectively guide the conversation. Third, because confidentiality and anonymity are not assured, respondents might feel uncomfortable expressing embarrassing or controversial opinions. Therefore, focus groups are at times not an appropriate method for controversial topics (Patton 2002).

2.13.5.3 Mental Models Interviews

Mental models interviews are a type of interview that can be used to assess farmers' perceptions of their vulnerability and adaptive capacity to climate shifts. The rationale for using mental models as an approach is the belief that the experiences people use to inform their decisions regarding complex issues are organized in a mental framework (or mental model) of associated or related concepts (Morgan et al. 2002). Mental models interviews are designed to capture current beliefs (correct and incorrect) without creating beliefs through the wording of questions, with the goal of visually displaying respondents' mental models. These visualizations, also called concept maps, allow comparisons to be made between groups, including the public and experts (Morgan et al. 2002; Bostrom et al. 1992; Lazo et al. 1999).

Mental models interviews, often used to understand risk perceptions, are typically semistructured interviews that begin with broad questions about the general topic of interest, to allow the interviewee to direct the flow of the conversation and express their views without the researcher imposing ideas or terms on the respondent (Morgan et al. 2002). A standardized interview guide should be developed and pretested with representative farmers and experts to ensure consistency across the interviews (Morgan et al. 2002). If the focus of the interviews is to identify gaps in the knowledge of farmers as compared to risk 'experts,' a mental model of agricultural vulnerability to climate variability could be constructed first, from interviews with these experts. Next, interviews would be conducted with farmers, and mental frameworks developed based on the expert model of vulnerability and adaptation to climate variability. This particular methodology does presume that experts have a more complete mental framework of the risks to agriculture from climate than do farmers.

Mental models interviews with farmers and experts about this topic might initiate with a question like, "Tell me what you think about the effects of climate variability on your farm" or even more broadly, "Tell me what you think about the effects of climate variability on U.S. agriculture." When there are particular areas of interest to the researchers, such as perceived vulnerability or adaptive capacity, specific prompts are included later in the interview guide so they can be addressed after the interviewee has had a chance to describe all of his or her initial thoughts about the broader topic.

The mental models diagrams constructed from these interviews highlights the similarities and differences between the vulnerability and adaptation frameworks of farmers and climate experts. Areas of consensus and divergence uncovered by the interviews could be used to inform policies and improve communication between climate vulnerability and adaptation experts and the farmers they are trying to persuade.

2.13.5.4 Participatory Approaches

Participatory approaches include numerous methods that involve research participants collaboratively in the research. Participatory approaches can be especially useful when the project goal is to achieve behavioral change or increase the usefulness of climate knowledge.

One participatory approach employed by Cabrera et al. (2008) is to involve participants in the development of models. In an iterative process involving scientists, farmers, consultants, and other stakeholders, the team of researchers created the Dynamic North Florida Dairy Farm model (DyNoFlo), a model used to help farmers make management decisions with the goal of reducing nitrogen runoff while promoting profitability. Their methods included exploratory interviews, site visits, focus groups, a *sondeo* or rapid rural survey (Hildebrand 1981), and farmer trials of a prototype model. Because stakeholders were involved throughout the process of model development, the resulting DyNoFlo model was usable and useful to farmers.

In another good example of how interaction between researchers and producers can increase understanding and accessibility, Ziervogel (2004) used a role-playing game to investigate how smallholder farmers in the African country of Lesotho would likely use seasonal forecasts in farm and household decision making. The role-playing game was conducted with small groups. First, participants collaboratively drew maps of their village. Then, three rounds, each representing 1 year, were commenced with a mock radio address announcing that season's forecast. During each round, participants were asked to look at the map and describe the farming and household decisions they would make based on the given forecast. Although the resulting data were hypothetical, there are a few advantages to using a role-playing game in lieu of a survey. Namely, the speculative decision making is given more contextual realism in that participants are interacting and communicating with others, responding to the mock forecast, and using a map to think about resources (Ziervogel 2004).

It would be futile to study farmer vulnerability and adaptation to climate variability without considering the benefits of the research to the farmers. According to Roncoli (2006), the aim of participatory research is to create change in the study community. Although qualitative and participatory studies do not lend themselves to generalizability and replication, they often result in participant learning and empowerment.

2.13.6 Case Study: Understanding Vulnerability and Adaptive Capacity to Enhance Usability of Climate Information in the North Central Region of the United States

The goal of the Useful to Usable (U2U) project is to improve the resilience and profitability of grain farms in the north central region of the United States amid variable climate through the development and dissemination of decision support tools, resource materials, and training. The U2U project consists of a diverse group of state climatologists, crop modelers, agronomists, economists, and social scientists who are working collaboratively to develop decision support tools that are usable by farmers and their advisors and that meet their needs. Building on the findings of the studies reviewed in this chapter, the U2U project is collecting information from potential users that will help to develop tools that will actually be used to improve adaptive capacity and reduce vulnerabilities.

Because the study area is too large to conduct in-depth participatory research, team members are initially surveying farmers throughout most of the region. However, the working hypothesis is that farmers may not ultimately be the ones using climate information in decision making and so there is a strong emphasis on finding out the needs of advisors – including extension agents, crop consultants, bankers, employees of the US Department of Agriculture, agricultural retailers, and others. Surveys of advisors are being conducted in four key states in the region. Both the producer and advisor surveys seek to find out when in the calendar year key farming decisions are made, whether people already use climate information in their planning, and what are current levels of adaptive capacity. To further understand how decisions get made and who influences producers, a stakeholder network analysis will also be conducted in these four states.

After gathering and analyzing the survey data, climate model developers and social scientists will work together to develop decision support tools that meet the expressed needs and interests of end users. High resolution, gridded crop models will be developed for the region and the impact of climate and management decisions on crop yield and farm profitability will be determined for four representative farm types. Based on the calendar information that emerges from the surveys, the goal of the modeling will be to provide information to people at critical times of the year to help with both short- and long-term farm planning decisions. Outreach and training materials will be targeted at appropriate audiences (producers, advisors, or both) based on the outcomes of the network analysis. Recognizing that a participatory approach is ideal for developing tools that can actually change behaviors and increase adaptive capacity, the team will work interactively with producers and advisors to evaluate and adapt these tools and outreach materials in an iterative process of co-production in four states. In-depth interviews and focus groups will be used throughout this iterative process. Only after the tools are clearly meeting needs in the four-state region will dissemination be extended across the entire 12-state region. This ambitious project is funded primarily by the USDA's National Institute of Food and Agriculture started in early 2011. More information can be found at www.agclimate4u.org.

2.13.7 Conclusion

Gaining a better understanding of farmers' vulnerabilities and adaptive capacities is essential for developing climate information that they can and will use to adapt. The literature review presented in this chapter illustrated that it is not always straightforward for farmers to use climate information. Only by better understanding gaps in adaptive capacity can these gaps be addressed. To that end, key social science methods such as the ones presented in this chapter can be used to identify and understand current levels of adaptive capacity. With this knowledge, the promise of collaboration with climate model developers to prepare climate forecasts and information in ways that farmers can use to improve their adaptive capacity can be fulfilled.

Glossary

Kharif crops Crops that are grown during the rainy season are 'Kharif' crops. Kharif crops are usually sown with the beginning of the first rains in July, during the south-west monsoon season.

Rabi crops The term is used in the Indian subcontinent for agricultural crops which are sown in autumn and harvested in the winter season. Crops that are grown during the winter season are called as 'Rabi' crops.

Dhencha 'Dhencha' is a local name for 'twigs of Sesbania.' The plant thrives on waterlogged soil and is grown in areas under reservoir submergence areas. It increases the total nitrogen, organic matter content of the soil in which it is planted, thus increasing the yield of the subsequent crop. It is also extensively used as a green manure for fish cultivation in India.

PRECIS PRECIS is a regional climate modeling system used to generate high-resolution climate scenarios at a regional scale. It is useful to identify how a country or a region can best adapt to the climate change–related impacts.

Taag Taag is a local name for sun hemp. It grows very fast and provides nutrients to the soil. Like Dhencha, it is also used as a green manure crop.

2.14.1 Introduction

Agriculture is closely linked to climate. Crops require optimal temperatures and moisture levels for their full growth. Changes in temperatures, precipitation, and seasonal variations will have adverse impact on the food crops and decrease their productivity. With the increasing pressure of meeting the demands of growing population, climate change is expected to bring new challenges for India's agriculture sector.

Agriculture is the primary occupation in rural India and a source of livelihood for two-thirds of the country's population. The sector therefore, remains an important component of the poverty strategies such as Millennium Development Goals (MDGs). The vulnerabilities in agriculture are not just limited to production losses, but have a major socioeconomic impact. This chapter discusses the existing vulnerabilities and risks that the agriculture sector in India is facing and assesses the potential risks due to climate change. The study concludes that adaptation to climate change should also act as a measure for bringing livelihood reforms and reduction of poverty. Building on traditional practices and local technological innovations will help in rooting the interventions and upscale them.

The chapter is presented in six sections. Section 2.14.1 provides an introductions and setting of the context. Section 2.14.2 outlines the profile of agriculture sector in India with recent trends and characteristics of various agroclimatic zones. This section also outlines key issues in agriculture in the country. Section 2.14.3 presents an assessment of existing vulnerabilities and associated risks. Assessment of projected impacts on production patterns of major crops along with cross-sectoral and other associated impacts is presented in Section 2.14.4. Section 2.14.5 discusses various strategic interventions to respond to climate change. Key learnings from the research are presented as concluding remarks in Section 2.14.6.

2.14.2 Profile of Agriculture Sector in India

Agriculture contributes to about 30% of the national income and 8.56% of the country's exports which include rice, cashew nuts, tea, horticulture, and floriculture products (GoI 2006). About 58% of India's population depends on agriculture for their subsistence. Considering the fact that out of 1210 million of India's population, 833 million (i.e., 68.84%) reside in rural areas, agriculture has a major role to play in enhancing the rural economy (Census 2011).

The share of agriculture in the country's Gross Domestic Product (GDP) is 14.2%. However, in the recent years this share is seen to decline. The main reasons behind this decline are the rapid growth of population and the growth of industrial and service sector economy (GoI 2011). In the near future, producing enough food for meeting the increasing consumption demands of the growing population is going to be a major challenge for the country. **Figure 1** shows that out of the total area of 140.86 million hectares (MH) under cultivation only 62.29 MH land is under irrigation whereas the remaining 78.57 MH (about 56%) is rain fed. This statistics indicates high vulnerability to climate change.

2.14.2.1 Major Agroclimatic Zones in India

Agriculture in India is heavily dependent upon the monsoons. The south-west monsoonal winds are the main source of rainfall to the country. Although some rainfall is also brought by the south-east winds, the proportion is far less. The amount and distribution of rainfall during the monsoon period are the key determinants for the production of food grains. The summer monsoon (Jun.–Sep.) contributes 78% of India's annual rainfall and is a major source of water (GoI 2004).

As a part of the Seventh Five Year plan (1985–90), the Planning Commission of India, divided the country into 15 broad agroclimatic zones. The zones were delineated on the basis of climate, physiography, resource development and utilization, and resource constraints and potentials (Planning Commission 1989). **Figure 2** indicates the list of zones identified on this basis. There is a large variation in the climate, topography, and soil conditions across the agroclimatic zones.

This has led to wide distribution in the type of crops, yield, varieties grown, and farming practices across the zones.

2.14.2.2 Trends in Agriculture

In terms of geographical spread, about 43% of country's land is used for agriculture purposes. However, huge population size creates a gap in the demand and supply of food grains. India holds only **2.3% share in the total land area of the world while it hosts about 17.5% of the world's population** (second largest in the world). It is estimated that the requirement of food stock to feed India's projected population of 1.4×10^9 in 2030 will be 114 million tons of rice, 83 million tons of wheat, 13 million tons of maize, 106 million tones of fruits and 193 million tones of vegetables (TERI 2005 as cited by Kelkar, 41 pp.). **Considering the situation of land availability and irrigation, maintaining the food security is going to be a major challenge.**

To cater to the increasing demand of food supplies, the Department of Agriculture (DoA) has taken steps to increase the percentage area of land under cultivation. The Green Revolution program initiated in 1967, focused on increasing the country's food production. The overall production of the country increased during this time. The key reasons attributing to this increase were expansion of agricultural land, development of high yielding and drought proof varieties, increased use of fertilizers and biocides, and improved irrigation systems. Under the Green Revolution, an additional 22.48 MH of land was brought under agriculture and 36.49 MH under irrigation. The food production increased from 50 million tons in 1951 to 212 million tons in 2012. During this time, the mean cereal productivity also increased from 500 to 1800 $\mathrm{kg\,ha^{-1}}$ (GoI 2004).

Although the Green Revolution has contributed to a significant rise in the food production, the production was confined to irrigated areas only. Further, excessive use of chemical fertilizers, pesticides, and genetically modified seeds reduced the fertility and crop production capacity of the soil. The long-term impacts of these interventions were found to be adverse or negative.

Further, only 25% of the farmers produce 60% of the country's total agricultural output (TERI 2005 as citied by Kelkar 2006 40 pp.). As per the 'All India Report on Agriculture Census 2005–06' (GoI 2012), the numbers of operational landholdings in 2005–06 have increased from 120 million (2000–01) to 129 million (2005–06). However, about 83.29% of these are small and marginal holdings (i.e., below 2 ha) and only 15.86 and 0.85% are semi-medium and large holdings, respectively.

Most of the irrigated lands are owned by large farmers who constitute to a very small proportion of the farming community. **India's agriculture is thus characterized by small landholdings with majority of the farmers practicing subsistence agriculture.** These farmers do not have a direct access to the markets. A large share of their farm profits is taken by people who act as middle man/intermediaries for selling the agricultural produce in the markets. Since the economic condition of these farmers is poor, they are not able to afford the cost of adopting new technologies and irrigation. Further, since rain-fed varieties grow only once in a year, the agricultural production is limited only to half the capacity.

2.14.2.3 Government's Initiatives in Agriculture

Government of India (GoI) has taken various policy-based initiatives for improving the socioeconomic condition of poor farmers. Welfare schemes related to health, education, banking, infrastructure support, markets, transport, etc., have been made. These policies and schemes have made some contribution to alleviate the situation of poverty and improve the condition of agriculture; however, these initiatives were isolated (without strong interconnections/linkages) and hence did not receive much success.

The policies and schemes implemented so far focused on increasing the production levels and subsidizing the costs for small and marginal farmers. This has led to rapid production of food grains resulting in degradation of land. Unfortunately, the subsidies provided increased the dependency of the poor farmers.

To make agriculture sustainable and a profit-making enterprise, a transformation in policy and decision making is required. The policies and programs should focus on developing the capacity of the small and marginal farmers. **While doing so, a shift from subsidy to investments is required. Efforts to improve the knowledge in agribusiness, improved management practices, input management, marketing, supply chain, information, etc., are necessary.** Certain forms of subsidies such as under pricing of water and zero/low pricing of electricity for pumping water may be still needed. However, rationalization of these subsidies with sectoral investments will be appropriate. The Eleventh Five Year Plan: 2007–12 prepared by Planning Commission (GoI 2008a) focuses on increasing sustained food production and shifting the subsidies to investment-based approach.

2.14.2.4 Key Issues

2.14.2.4.1 Increasing Frequency of Droughts and Floods

About one-third of the land in India is either drought or flood prone. Figure 3 (a) and 3(b) provides the geographical spread of the drought and flood prone districts in India respectively. In the past 50 years, the country has faced 15 major droughts and 7 severe floods (GoI 2004). The average rainfall of the country is 11, which is 39 mm higher than the annual global average; however, the regional variation in the pattern of rainfall is rather high. About 73% of the annual rainfall is received in less than 100 days; whereas 33% of the cropped area identified as chronically drought prone receives less than 750 mm annual rainfall. In these areas, even a rainfall of 400 mm would be adequate for the growth of crops, while in a high rainfall place such as Assam, a rainfall of even 1000 mm would not be sufficient and may create situations/conditions of droughts (GoI 2009) (**Figure 3**).

The National Flood Commission's (NFC) Report (1980) indicates that 40 MH of the land is prone to flooding. The flood zones are largely situated along the Indo-Gangetic plains, north-eastern states, and at some sections in the central river basins.

Between the periods of 1955–2004, the average crop area of 3.59 MH was affected due to the flooding. The crop area affected during 1988 was 10.15 MH. Another period when the flood impacts were severely felt was the period of 1976–78. A total of 4.105 MH of land came under flooding. The estimated crop damages were Rs. 786 millions (NFC 1980).

The assessment of the rainfall pattern shows that 68% of India is vulnerable to droughts. The drought areas extend over the western and peninsular regions of Rajasthan, Gujarat,

Orissa, Maharashtra, Andhra Pradesh, Jammu & Kashmir, Himachal Pradesh, and Bihar (Mahapatra 2001). The year 1987 was one of the most severe drought years. During this year, the rainfall deficiency was 19%. About 59–60% of the crop area was affected and 285 million people were impacted. In the recent years, the drought of 2002 was the most severe. The rainfall deficiency during the monsoons was 51% (lowest in the history). The production of food grains declined to 29 million tones, whereas the estimated financial loss to agricultural income was Rs. 390 000 millions (Samra 2004 as cited in GoI 2009, 13 pp). The early season droughts, i.e., when rainfall deficiency is observed in the months of Jun.–Jul., provide sufficient time for the farmers to mitigate the adverse situations, as compared to the late season droughts where rainfall is scarce during the month of September.

Although rainfall variation is one of the key reasons for arising of drought and flood situation in India, other reasons such as depletion of forests, poor water management strategies, overexploitation of the ground and surface water resources, poor irrigation systems, inadequate infrastructure, etc., have lead to increasing the vulnerability.

Climate change is further expected to distort this cycle of droughts and floods. The rise in temperatures and increase in intensity of the rainy days will result in spatial and temporal variations in climate, thereby adversely impacting the cropping cycle and production levels.

2.14.2.4.2 Security of Food

The food security for India is already under threat with the recurrence of droughts and floods. The growing increase in population and distortion of drought and flood cycle would further induce an additional stress. If the population continues to grow at this rate, by 2020 the demand for key food crops such as rice, wheat, coarse grains, and cereals is estimated to rise substantially.

The estimated demand for food crops for 2020 against the production achieved in 2000 is estimated to grow by about 37 Mt for rice and 32 Mt for wheat. The demand for fruits and vegetables is estimated to grow by 36 and 65 Mt, respectively. The demand for milk and milk products is expected to grow by 67.5 Mt (GoI 2004 83 pp.). **Figure 4** provides a graphical representation of the production and demand of food crops in the country. Considering that the total area under agriculture will not increase, feeding the increasing population is going to be a real challenge for the country.

To meet the increasing demand, there is a need to develop an effective drought and flood management system, which could prevent/control the losses of food production. This would include developing early warning systems, flood control mechanisms, drought resistant varieties, and increasing the agricultural productivity in general.

2.14.2.4.3 Degradation of Land

The issue of land degradation is further contributing to the loss of production. The annual rate of growth in food production and yield peaked during the early years of the Green Revolution, but it has declined since the 1980s (GoI 2004 83 pp.). Some of the main reasons for this are use of harmful pesticides and fertilizers that affected the fertility levels of the soil after the initial harvests, indiscriminate extraction of groundwater leading to reduced water tables, and increased salinity of the soil. The mid-term assessment of the 11th Five Year Plan (GoI 2008a) suggests that the fertilizers used for enhancing the crop production has led to micronutrient deficiencies in the soil, leading to reduced capacity of crop growth and production. According to a study conducted by Ajai et al. (2009), out of the country's total geographical area of 328.73 million, 57% is either desertified or degraded. An optimum mix of fertilizer, along with sound crop management practices is required for reducing the issue of land degradation.

2.14.2.4.4 Increasing Poverty

Poor farmers practice subsistence agriculture and usually have a hand to mouth living. Their annual year's income is

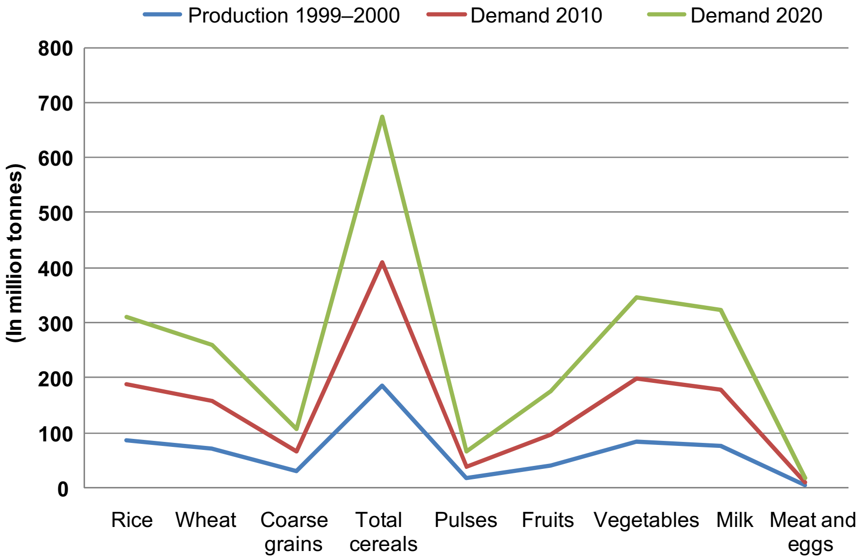

Figure 4 Food production and demand for key crops in India. Data source: Government of India (GoI), 2004: *Vulnerability Assessment and Adaptation, Chapter 3, India's Initial National Communication to the United Nations Framework Convention on Climate Change*, Ministry of Environment and Forests, GoI, New Delhi.

dependent on monsoons. Any changes in the rainfall and temperature extremes can impact the crop production and adversely impact their livelihoods. Since they do not have alternate sources of income as a coping mechanism, they are often forced to sell their assets such as livestocks, lands, or migrate in urban areas, where they have to settle in marginal and highly vulnerable areas. This increases the vulnerability and the situation of poverty. The situation is further grave for agriculture laborers. In India, about 50–75% of the labor population is dependent on agriculture. Increased vulnerability of agriculture to climate change will adversely impact the livelihoods of the small and marginal farmers, and the labor population who are highly dependent on this sector. It is necessary that along with improved agricultural facilities, these farmers and labor populations are provided with alternate sources of livelihood and social security, such as improved access to health care, education, and other facilities.

2.14.3 Existing Vulnerabilities

2.14.3.1 Over dependency on Agriculture

The agriculture sector in India is subjected to various stresses such as increased pressures for availability of land, water, and labor. This coupled with an increase in temperatures and precipitation will result in a negative impact on the food production. Although the share of agriculture in the country's GDP is 14.6% (GoI 2011) it contributes to approximately 45.5% of the employment (GoI 2010).

Considering the fact that approximately 67% of India's population depends on agriculture and related activities for livelihoods, a slow rate of growth of the agriculture sector is a concern. Hence, there is a need to diversify into other activities such as livestock farming. For instance, dairy and poultry enterprises could provide substantially higher financial returns than crop farming. Further, such enterprises can help create new jobs and bring about health and nutritional improvements in the families.

2.14.3.2 Requirement of Improved Infrastructure, Technology Transfer, and Extension Services

Practices adopted for increasing agricultural yield have turned out to be neither economically nor environmentally sustainable. Access to improved quality of infrastructure such as cropping technologies, seeds/crop sampling varieties, electricity supply, farm machinery, policy-based incentives, research in traditional farming methods, etc., will help in improving the crop production and reduce the vulnerability. Besides this, there is a need to develop forward and backward linkages with the traditional and modern technologies. For example, the crops grown using chemical fertilizers and genetically modified species, could lead to high risks, as these interventions could reduce soil fertility and lead to adverse health impacts. The crops grown using traditional knowledge and indigenous varieties may not pose such risks, albeit at a disadvantage of lower yields. This is where technology innovations and pilots are necessary.

There is a need to revisit the knowledge used in our traditional farming methods and update it to suit the current production requirements and climate variability. The linkages thus developed would help to reduce the technological gaps in farming. The farmers at the grassroot levels have often devised their own ways to meet the resource constraints posed due to adverse climatic situations of a place. The technological innovations carried by them are well rooted with the geography, climatic situations, and resource constraints. The techniques and methods are often simple, cost effective, and have a high potential to upscale. There is a need that such innovations are tapped and supported with necessary engineering technology, policy, and financial arrangements. Further, provision of extension services such as developing market linkages, access to credits for small and marginal farmers could help to reduce the financial vulnerability, and help in sustaining the high productivity on a long-term basis.

The technology transfer and adaptation at various levels with a collective approach of government, agriculture scientist, researchers, nongovernment and private sector agencies, and farmers will help to achieve this.

2.14.3.3 Gap in Demand and Supplies

One of the main challenges facing India is producing enough food for the increasing population. Import of basic commodities such as rice and wheat is increasing. Rapid increase in the population has induced additional stress on the food supplies. Since the land available for agricultural produce is limited, the focus has shifted to increasing the production capacity. This has led to the introduction of new crop varieties providing high yields. However, irrespective of these efforts, the shortage in food supplies is persistently increasing. This has led to increase in the prices of food grains and other agricultural commodities. There have been some adjustments by the government to control the escalation in the prices of major crops; however, the gap between the demand and supply is widening.

2.14.3.4 Dependency on Monsoons

Increased use of irrigation however has helped India increase average yields. About one-third of the cropland in India is irrigated, but rain-fed agriculture is still central to the economy. Harvests and national prosperity have traditionally depended on a successful south-west monsoon, which is the source of about three-fourths of India's annual rainfall.

As of 2010, only 40% of the net sown area of 141 MH has an access to irrigation, while the remaining 60% is rain fed (GoI 2011). For the areas, which are irrigated, the allocation of water is inefficient, unsustainable, and inequitable. This has reduced the potential of growing multiple crops within a year.

Further, the monsoonal rainfall is very inconsistent and unevenly distributed. Increased variability of the summer monsoons has directly impacted the agriculture yield. The National Commission on Agriculture in 1976 has estimated that the rainfall variations accounted for 50% of the variability in agricultural yields, being as high as 90% for cotton and groundnut, 47% for wheat, and 45% for barley and jowar. Since the majority of the rain-fed varieties is grown in small landholdings, it has a direct impact on the livelihoods of the small and marginal farmers whose earnings are largely dependent upon the net crop produced during this time.

2.14.3.5 Disaster-Related Vulnerabilities

Increase in the frequency of disasters will entail higher economic and financial risks for farmers. Disasters such as droughts and floods have resulted in huge economic losses. In India, two-thirds of the total area under cultivation is prone to droughts and about one-fourth of the cropland is prone to flooding. As per the study conducted by National Center for Disaster Management (NCDM) and National Disaster Management Division (NDMD), in 1999, 40 MH of land is prone to floods and about 30 million people are affected each year on an average (NCDM and NDMD 1999).

The capacity to restore the livelihoods and initiate new livelihood options is rather low. In addition, new disease vectors may proliferate that could further reduce the capacity of earnings from livestock and related sources.

The adaptive capacity of the farmers mainly depends upon the farmer's socioeconomic condition and the access to infrastructure, finances, and insurance. As per a study conducted by TERI (2003), it was found that except for the State of Bihar, all the districts falling under the Indo-Gangetic plains have a higher adaptive capacity. The adaptation capacity is found to be extremely low for the states of Rajasthan, Gujarat, Madhya Pradesh, and western parts of Maharashtra, Andhra Pradesh, and Karnataka. Vulnerability of the north, north-eastern, and southern states is lowest. The study reveals that districts, which are highly sensitive to the climatic variables, are not necessarily the ones with high vulnerability and vice versa (O'Brien et al. 2004).

2.14.3.6 Biophysical Vulnerability

The agriculture produce in India largely depends on large irrigation projects and use of chemical fertilizers for increasing the harvest. While doing so, conservation of natural soil nutrients, water resources, and water holding capacity are largely neglected. Clearly, this type of practice is not sustainable as it leads to degradation and contamination of land resources on a long run. The crops grown by making use of excessive chemicals extract more water and do not recharge the groundwater. In order to extract more production, the crops grown were of the same varieties, which extract the soil nutrients, unlike traditional cropping where crops are grown on a rotational basis and intercropping is done to increase the crop variety.

The life cycle assessment of this cropping shows that due to the presence of harmful chemicals the residues of such crops cannot be used for any other purpose such as fodder for cattle. The use of sprays and chemicals to increase production kills the bacteria and fungus in the top soil layer thereby reducing the fertility of the soil and its capacity to grow the next crop. **Although increasing the food production is important, achieving it in a sustained manner is equally important. Production should be increased without damaging the soil nutrients and water. The focus therefore has to shift from high yield giving chemical fertilizers to the sustained yield given by organic fertilizers.**

2.14.3.7 Slow Growth in Agroeconomy

Although agriculture is the backbone of India's economy, dependency on agriculture for employment is decreasing gradually. Sustenance of small and medium farmers is difficult, if appropriate policies and programs along with a strong institutional delivery system are not developed in time.

As discussed earlier, the current agricultural practices are neither economically nor environmentally sustainable. This has resulted into poor yields and increase in commodity prices. Poorly maintained irrigation systems and almost a universal lack of good extension services are among the key factors responsible for the slow growth of the agriculture economy. Further, the farmers are not able to get the right price for their produce as their access to markets is hampered by poor roads, rudimentary market infrastructure, and excessive regulation (The World Bank 2008).

2.14.3.8 Low Productivity

Since the cultivable area is limited the focus is on enhancing the crop yield or productivity. However, it has been observed that the productivity is high only for large and medium landholdings and having an access to irrigation facilities; whereas the production of small and marginal landholdings continue to remain low.

A study conducted by The World Bank (2008a) suggests that there are multiple reasons behind the low productivity in agriculture sector. One of the main reasons is **the large number of agricultural subsidies that has in fact reduced the productivity–enhancing investments. The technologies for improved and sustained food production are being used to a limited extent. A widespread knowledge of such technologies has also been missing. The main reasons for these impediments are high costs, illiteracy, slow progress in implementing land reforms, inadequate or inefficient finance, and marketing services for farm produce, and impracticality in the case of small landholdings.**

2.14.4 Impacts of Climate on Agriculture

Agriculture is extremely sensitive to the impacts of climate change. A small variation in the rise/fall in temperatures and precipitation levels can reduce/damage the crop growth. The carbon dioxide concentration in the atmosphere also has a significant impact on the growth of the crops.

These impacts can be broadly classified as direct, indirect, and socioeconomic impacts. The direct impacts are the ones, which are felt through direct changes in temperature, water balance, carbon dioxide concentrations, and extreme weather events. These parameters can have an adverse effect on growth, structure, and life cycle of the crops. The indirect impacts are shown with the outbreak of crop diseases, decrease in the quality and quantity of crop production, reduced fertility of soil, emergence of pests, weeds, insects, diseases, etc. The socioeconomic impacts are the cumulative effect of both the direct and indirect impacts. This includes shortages in food supplies, loss of livelihoods, reduced income, increased exposure to disease vector, etc. Figure 5 represents the linkages between these impacts and development of adaptation and mitigation strategies.

According to IPCC fourth assessment report (IPCC 2007), the earth's temperature has increased by 0.74 °C between 1906

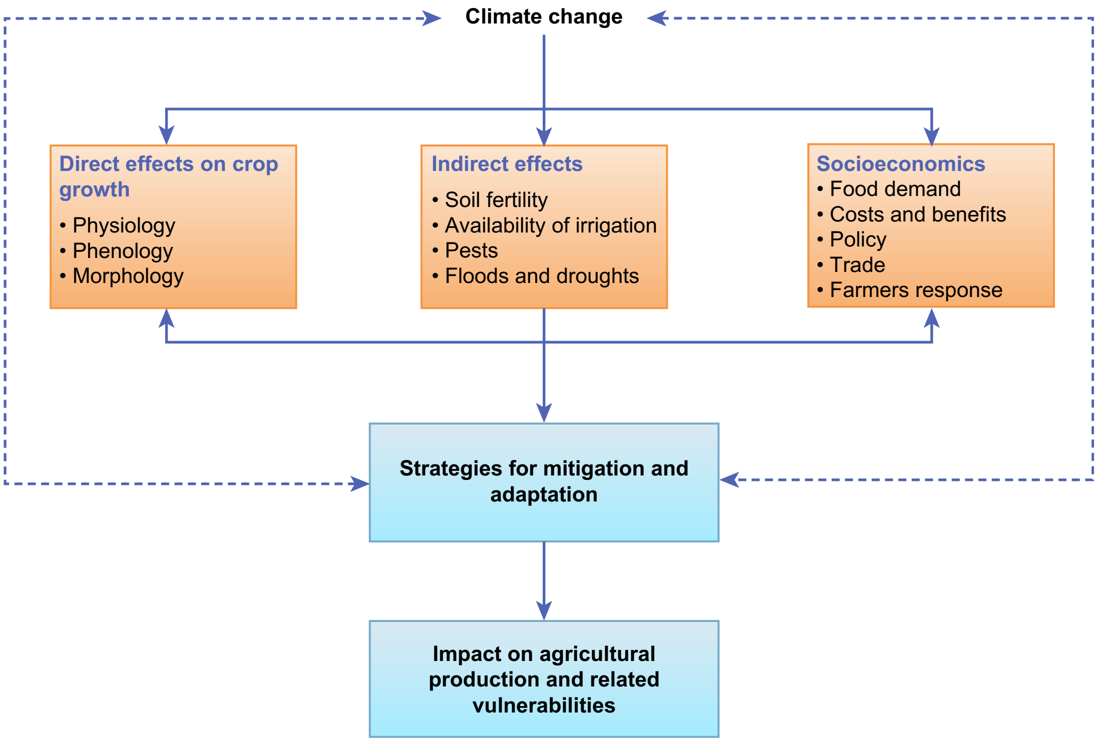

Figure 5 Assessment of vulnerability of agriculture to climate change. Adapted from Department of Environment Food and Rural Affairs (DEFRA), 2009: *Climate Change Impacts on Agriculture in India*. Department for Environment, Food and Rural Affairs, Government of United Kingdom. [Available online at http://www.decc.gov.uk/assets/decc/what%20we%20do/global%20climate%20change%20and%20energy/tackling%20climate%20change/intl_strategy/dev_countries/india/india-climate-6-agriculture.pdf, retrieved on 12 July 2010.]

and 2005 due to increase in anthropogenic emissions of greenhouse gases. It is estimated that the increase in temperature will result in 10–40% decrease in production of food grains by AD 2100.

In the case of India, the temperature data collected by the Indian Meteorological Department (IMD) for the last 100 years show warming of 0.5 °C over Indian region (GoI undated). The future climate change projections for 2070–2100, based on application of PRECIS by Indian Institute of Tropical Meteorology (IITM), suggest a change of 3–5 °C, in the annual mean surface air temperature and a 20% rise in the summer monsoon rainfall.

In the case of Rabi and Kharif crops, the mean temperature is projected to increase by 0.10–0.30 °C in Kharif (summer) and 0.30–0.70 °C in Rabi (winter) by 2010 (IPCC 1996). There is a possibility that this trend may increase in 2070 where the mean temperatures during Kharif and Rabi seasons will fall between 0.40–2.00 °C and 1.10–4.50 °C, respectively (GoI 2004). Table 1 presents an assessment of the relationship between decreasing rainfall and net production of Kharif crops in the years of deficient rainfall. It has been observed that for an average deviation of 17% rainfall, the corresponding change in food grain production is about 11%. The mean rainfall is projected not to change by 2010, but has a possibility to increase by 10% by 2070 for the Rabi season. At the same time, there is an increased possibility of climate extremes, such as the timing of onset of monsoon and increased intensity and frequencies of droughts and floods (GoI 2004).

2.14.4.1 Sensitivity of Indian Agriculture to Climate and Possible Changes

Climate change can adversely impact the production of crops such as wheat, rice, and pulses in India. It is projected that there is a possibility of about 10–40% loss in crop production in India by 2080–2100 due to global warming (Fischer et al. 1994; IPCC 2007). Also a few other Indian studies by Aggarwal

Table 1 Impact of rainfall variation on crop production for Kharif season in India

Deficient rainfall years	*Monsoon rainfall % departure from normal*	*Rainfall in July*	*Kharif food grain production % fall*
1972–73	−24	−31	−7
1974–75	−12	−4	−13
1979–80	−19	−16	−19
1982–83	−14	−23	−12
1986–87	−13	−14	−6
1987–88	−19	−29	−7
2002–03	−19	−49	−19

and Sinha (1993), Saseendran et al. (2000) and Aggarwal and Mall (2002) confirm a similar trend.

Table 2 presents highlights of the various studies undertaken to assess the impacts of climate change on Indian agriculture. Almost all these studies confirm that the economic losses to agriculture will increase and will be significant.

About 1.5–2° increase in temperatures will heavily impact the production of wheat, whereas increasing levels of precipitation will impact the cultivation of rice. As per the study conducted by Aggarwal et al. (2009), for every 1° rise in temperatures, the possibility of losses in the wheat production is estimated to be about 4–5 million tons. In the IPCC third assessment report, a study conducted by Saseendran et al. (2000) stated that with 1.5° rise in temperature and 2 mm increase in precipitation, the yield of rice is expected to decrease by about 3–10%.

The food production in the coastal areas especially the coastline along Gujarat and Maharashtra along with parts of Rajasthan, North Karnataka, and Andhra, Madhya Pradesh is expected to be impacted more than other states. In 2004, there were instances of reduction in the crop production, in the Indo-Gangetic plains due to a rise of 3–6 °C, i.e., about 1 °C per day over the whole crop season. This led to about 10–20 days of early maturity of the crops, thereby reducing the overall wheat production by 4 million tons (Samra and Singh 2004 as cited in GoI 2010a 67 pp.).

In certain cases, the increase in carbon dioxide levels is expected to increase the crop production, however, there is a possibility that it would be nullified by the increase in temperature.

2.14.4.2 Impacts on Food Crops

The study conducted by the Department of Environment Food and Rural Affairs, DEFRA (2009), for understanding the impacts of climate change on India's agriculture shows that due to low coping mechanism in rain-fed agriculture, the reduction in yield as a result of climate change is predicted to be higher for rain-fed crops as opposed to irrigated crops. The difference in yield will be determined by the actual climatic situation. It is estimated that the probable losses will be high for areas where the baseline temperatures are higher. For regions where the temperature is relatively low, the yield is expected to decrease by about 1.5–5.8% (GoI undated).

The major food crops in India include wheat, rice, millets, and sugarcane. Studies have been undertaken to assess the climate change–related impacts on these. The study undertaken by Aggarwal et al. (undated) at the Indian Agriculture Research Institute (IARI) shows that wheat production in 2020 is set to decline. Production levels may increase up to 5% in the states of Haryana, Uttarakhand, parts of Uttar Pradesh, and Jharkhand. In some pockets of Uttar Pradesh and Uttarakhand, the increase is estimated to be 10%. The losses of wheat production will be predominantly felt in the regions of central Maharashtra, western Gujarat, and Rajasthan. In the absence of any adaptation measures, the trend is expected to further decline by 10–20%. The findings of this study are presented in Figure 6. The assessment of the results across various regions depicts that the production of wheat in the northern region will increase in the initial period (2020). However, this rise will be followed by a decline where the production may get reduced by 5000 tons. The amount of increase and decrease in the wheat production across four regional territories is presented in Figure 7.

India is the world's second largest producer of wheat and rice. About 20% of the world's rice production comes from India. Most of the country's rice produce comes from the southern states especially Andra Pradesh, coastal areas of Maharashtra, West Bengal, and Uttar Pradesh.

Rice is a water extensive crop. Delays in the arrival of summer monsoon and fall in night temperatures can have a negative impact on the country's rice production. Every 1° fall in night temperatures can reduce a 10% yield (Peng et al. 2004). Also spells of erratic and unseasonable rains can lead to about 50–100% yield loss (Annamalai and Shekar 2009).

Table 2 Assessment of climate-related impacts on India: key findings from various studies

GoI (2004)	● Wheat yields in central India may drop by 2% in a pessimistic climate change scenario. ● Decline in yields are offset by increase in carbon dioxide concentrations with the magnitude varying from one crop to the other in different regions, depending mostly on the scenario chosen.
TERI (2003)	● Districts in western Rajasthan, southern Gujarat, Madhya Pradesh, Maharashtra, northern Karnataka, northern Andhra Pradesh, and southern Bihar are highly vulnerable to climate change in the context of economic globalization. ● Numerous physical (i.e., cropping patterns, crop diversification and shifts to drought-/salt-resistant varieties) and socioeconomic (i.e., ownership of assets, access to services, and infrastructure support) factors come into play in enhancing or constraining the current capacity of farmers to cope with adverse changes.
IPCC (2007)	● Temperature rise of 1.5 °C and a 2 mm increase in precipitation could result in a decline in rice yields by 3–15%. ● Sorghum yields would be affected and yields are predicted to vary from 18 to −22% depending on a rise of 2–4 °C in temperatures and increase by 20–40% of precipitation.
Kumar and Parikh (1998)	● Economic impacts would be significant even after accounting to farm-level adaptation. The loss in net revenue at the farm level is estimated to range between 9 and 25% for a temperature rise of 2–3.5 °C.
Sanghi, Mendelsohn, and Dinar (1998)	● A 2 °C rise in mean temperature and a 7% increase in mean precipitation would reduce net revenues by 12.3% for the country as a whole. Agriculture in the coastal regions of Gujarat, Maharashtra, and Karnataka will be the most negatively affected. ● Possible losses are pointed out for the major food-grain producing regions of Punjab, Haryana, and western Uttar Pradesh.

Other impacts, which would be mostly prevalent in the coastal belt include increased salinity, due to intrusion of sea water and increased flooding.

The study conducted by Aggarwal et al. (undated) from IARI has calculated the net loss in production in 2020, 2050, and 2080. The bar chart presented in Figure 8 suggests a possible loss of 2.5% by 2020. The loss may increase to over 7% by 2050 and may go as high as 25% by 2080, which can become a major threat to food crisis since rice has a major share in the country's crop production. Timely adaptation measures can help to reduce the intensity of losses in future to a great extent. Figure 8 shows the reduction in the amount of losses expected after starting adaptation.

Amongst the other crops sugarcane and millets are some of the main food crops. Study conducted by the World Bank (2008) in the states of Maharashtra, Andra Pradesh, and Orissa shows that yields may drop by/up to 30%. India is the world's largest millet producer. The requirement of water for these crops is about 25% less in comparison to the main stream crops such as rice and sugarcane. Also, they can adapt to a wide range of ecological conditions and can be grown in all seasons. Millets can be grown in the poorest of the soils and are pest free. They do not require pesticides and fumigants for storages. Their growth is better in the absence of chemical fertilizers and grows mostly on farm land and biomanure. Millets have high nutritional value. While wheat and rice might provide only food security, millets produce multiple securities (food, fodder, health, nutrition, livelihood, and ecological) thereby increasing the agriculture security (Millet Network of India 2009). However, it is observed that the area for millet cultivation in India is shrinking, which is a concern. Considering the fact that millets are water saving and drought tolerant, it is important that they are promoted.

2.14.4.3 Impacts on Biodiversity

The change in temperatures and humidity will influence the biodiversity of a region. Insects and pathogens will change their behavior. Considering that crops are dependent on insects for pollination, the change in behavior will impact the yield of

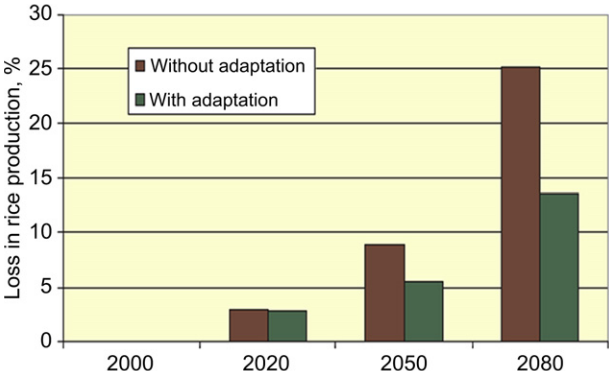

Figure 8 Possible impacts on rice production. Source: Aggarwal, P. K., et al., undated: *Vulnerability of Crop Yields in India to Climate Change*. Indian Agriculture Research Institute, New Delhi, India. [Available online at http://www.teriin.org/events/docs/wb_confer/73pk_agarwal.pdf.]

crops. In the case of crops such as sesame, litchi, mustard, and cashew the yield is substantially high when pollinated by insects. While crops such as sunflower, cloves, melons, beans, etc., are completely dependent on pollination by insects. The temperature changes can also influence growth of weeds and pathogens, which can further reduce the agricultural produce.

2.14.4.4 Cross-Sectoral Impacts
